HERO ID:	5901036			
Conditions of Use:	emission			
EXTRACTION				
Parameter		Data		
Description of release source:		Particleboard - Free formaldehyde , which is present in cured resin at low levels (<1%) is the most significant source of formaldehyde release from pressed-wood products in the initial period ,after they are manufactured.		
Release quantity:		Particleboard made by three different West German manufacturers was obtained by an NPA member company . The boards were all represented as E-1 grade, i.e., having emissions of 0.1 ppm or less. The three E-1 board samples were measured by large chamber methods at three different labs. The results showed that particleboard from Manufacturer A had an average emission of 0.19 ppm; particleboard from Manufacturer B had an average emission of 0.23 ppm; particleboard from Manufacturer C had an average emission of 0.17 ppm. The average of test readings for the German E-1 boards was 0.20 ppm, twice that of the E-1 standard.

Study Citation:	NCASI, (1986). Formaldehyde, phenol and total gaseous non-methane organic compound emissions from flakeboard and oriented-strand board press vents.			
HERO ID:	5904947			
Conditions of Use:	Wood production			
EXTRACTION				
Parameter	Data			
Description of release source:	Mill A produced waferboard. Aspen logs were flaked and dried to prepare the furnish. Liquid phenol-formaldehyde resin and wax were added to the flakes in rotary blenders. The resin application rate was 5.0 percent in the core and 4.75 percent in the surface material when the vents were sampled . The flakes were spread on platens, pressed, and heated in a 16 opening press. The press operated at 400°F and pressed mats that were 8 by 24 feet. The boards were unloaded and trimmed to their final size. Mill B produced waferboard. Lodgepole pine and cottonwood logs were flaked and dried to prepare the furnish. Powdered phenol-formaldehyde resin and wax were added to the flakes in rotary blenders. The resin application rate was 2.0 percent in both the core and surface material. The flakes were spread on platens and pressed and heated in an 8 opening press. The press operated at 400°F and pressed mats that were a nominal 8 by 16 feet. The boards were unloaded and trimmed to their final size.			
Release quantity:	Formaldehyde emission rates ranged between 0.17 to 0.56 lb/MSF. At Mill A the different resins used made a difference in the FA emission rate. Emission rates shown in Table B-1: When resin A was used the FA emissions averaged 0.30 lb/MSF actual and ranged between 0.25 and 0.38 lb/MSF actual and between 0.26 and 0.39 lb/MSF on a 3/4 inch basis. FA emissions were higher when Resin B was used. Insufficient data to compare between resins A and C. Table B- shows emission rates for Mill B - averaged 0.17 lb/MSF actual and ranged between 0.14 and 0.20 lb/MSF actual, and between 0.23 and 0.35 lb/MSF on a 3/4 inch basis. 2% resin was added to flakes, this resin contained 2% free FA. Of the free FA 30% was emitted through press vents.			
EVALUATION

HERO ID:	5904953
Conditions of Use:	Emissions (particle board press vents)

EXTRACTION

Parameter	Data
Description of release source:	Mill A produced standard and industrial grade particleboard. The board was formed in three layers. The outer layers contained more fines to create smooth surfaces. The inner layer contained coarser particles to maintain it's strength characteristics. This layering was achieved by two forming machines. Each machine projected the furnish in the appropriate direction so that the coarser material, carried by momentum, deposited where the interior of the board is being formed. UF resin in a partially polymerized state at 65% solids was blended with the furnish just prior to formation. A small amount of wax was added to bind the resin to the wood particles. The furnish was derived from Douglas-fir resident. Mills B and C description were not copied over into this document. Mill B - produced 2 gardses of particleboard during the study. 1st was a 55 lb/sq ft density board destined for commercial use. it was made in thicknesses between 0.5 and 1.25 inches. The 2nd was a 32 lb/sq ft density board used to make solid core doors. It was made in thicknesses of 1.25 to 1.5 inches. 2 dryers provided furnish for the board. The furnish was derived from aspen and ponderosa pine. The furnish was screened to segregate coarse material for the interior of the board and fine material for it's surface. UF resin was blended with the screened furnish in screw conveyers that transported it to hoppers. The surface material received 6.8% resin whereas the core received 8.8% when commercial particleboard was being produced and 9.2% when door core was being produced. When the door core was being produced a high excell formaldehyde content (high fuming) resin was used to reduce press time. This produced was not subject to the low FA off-gassing requirement of commercial grade particleboard. 6 forming heads laid the furnish on platens. The unpressed boards were trimmed to size and loaded in batches of ten into the press. After pressing they were trimmed and passed through a board cooler. The Press accepted ten boards at a time. The max board dimensions were 66 by 230 inches. The size of the board pressed changed with product specifications. The press was operated at 360 F for commercial particleboard and at 380 F for door core. The press pressure was 2600 psi for commercial particleboard and 1500 psi for door core. Mill C produced particleboard with 2 separate production lines. The mill produced premium and industrial grade particleboard during the emission tests. A UF resin and was added to the furnish in rotary blenders. The furnish was derived from western pine species and Douglas-fir. The resin application rate was 8.2% in the core and 8.9% in the surface material when the premium grade was produced. During production of the industrial grade, the resin application rate was 9.0 to 9.4% in the core and 9.1 to 10.3% in the surface material. 4 formers spread the furnish onto platens with fine material being placed on the surfaces and coarse material placed in the middle of the mat. The mats were pressed and heated in a 16 opening press. The press operated at 320 F and pressed mats that were a maximum of 64 by 216 inches, but were usually smaller. The boards were unloaded, cooled in rotary board coolers, and trimmed to their final size. Mill D - dried ponderosa pine particles were blended with was and 6.9% liquid resin. Three formers laid down surface, core, and surface material sequentially to form mats. The mats were placed into an 18 opening hot press and pressed into particleboard. The press operated at 315 and 335 F. The boards were unloaded, trimmed and stacked.
Release quantity:	3 factors affected FA emissions from the press vents: excess FA content of the resin, amount of resin used and press temperature. Across all mills FA content ranged between 0.30 to 1.20 lb/MSF. Figure 3 provides FA emission rate as a function of board resin content and figure 4 is FA emissions as a function of excess FA in the board. FA emission rates at Mill A averaged 4.4 lb/hr and ranged between 3.1 and 6.3 lb/hr with average emissions of 0.39 lb/MSF board produced and ranged between 0.32 and 0.48 lb/MSF. Corrected to a 3/4 inch thick product, the FA emission rate ranged between 0.25 and 0.60 and averaged 0.42 lbs/MSF. Mill B - average for production of commercial particleboard was 6.9 lb/hr and during manufacture of door core was 16.2 lb/hr. In terms of emissions per actual unit production these average emission rates were 0.75 lb/MSF and 2.2 lb/SF for the commercial particle board and door care grades respectively. On a 3/4 inch basis they were 0.70 lb/MSF and 1.1 lb/MSF respectively. Mill C - average of 6.8 lb/hr and ranged between 5.0 and 8.2 lb/hr. Expressed in terms of production averaged 0.33 lb/MSF actual, ranged between 0.20 and 0.40 lb/MSF actual, and between 0.22 and 0.81 lb/MSF on a 3/4 in basis. Mill D - FA emissions average 6.5 lb/hr and ranged between 5.2 and 7.3 lb/hr. Emssion rate was 0.33 lb/MSF actual and ranged between 0.29 and 0.39 lb/MSF actual, and between 0.44 and 0.53 lb/MSF on a 3/4 inch basis.

Domain 1: Reliability	Metric 1: Methodology	Medium	The release data methodology is expected to be accurate but does not cover all release sources from a site just an emission factor from one potential source.	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States	
	Metric 3: Applicability	Low	The release data are for a non-occupational scenario (i.e., the study did not include information that process/site would heat the polyurethane foam) but that may be useful for occupational scenarios within the scope of the risk evaluation.	
	Metric 4: Temporal Representativeness	Low	are more than 20 years old	
	Metric 5: Sample Size	Medium	characterized by a range with uncertain statistics. It is unclear if analysis is representative.	
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Release data include most critical metadata, including release media; activity that is the source of the release; but lacks release frequency.	
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Low	The release data study does not address variability or uncertainty.	
Overall Quality Determination		Low		

Study Citation:	NIOSH, (1984). In-depth survey report: Control technology for formaldehyde emissions at Dixie Furniture Plant, Lexington, North Carolina.			
HERO ID:	8728028			
Conditions of Use:	Adhesives and sealant chemicals in wood product manufacturing			
EXTRACTION				
Parameter	Data			
Description of release source: Formaldehyde is emitted while the boards are being pressed, although the escape of vapors is restricted by the closed press. Much formaldehyde vapor is released when the press opens. The emissions of formaldehyde from the hot boards continues as the boards are unloaded, stacked, and cooled. (7/22)

HERO ID:	4084759			
Conditions of Use:	use			
EXTRACTION				
Parameter	Data			
Description of release source:	foundry waste sands			
Release quantity:	Data was obtained from two foundries - Foundry P was using phenolic alkaline resin (PR) and foundry F was using furanic resin (FR). Results showed that the phenolic alkaline process generated waste sands with higher formaldehyde content than the furanic process; the highest value was 7.6x10^-3 % (w/w). In this work, formaldehyde content decreased with time in all of the samples studied, revealing that most formaldehyde was released to the occupational environment. The samples with the highest formaldehyde percentage in the FR process was 1.3x10^-3 - 2.0x10^-3 %. Four of these samples were waste fines of reduced dimensions, obtained after thermal and/or mechanical treatment; all of these sands had been submitted to high casting temperatures. Results of the analysis of PR samples on the first days show the highest formaldehyde content for a fine sand obtained after thermal treatment (7.6x10^-3 %).

HERO ID:	5587959			
Conditions of Use:	emission			
EXTRACTION				
Parameter	Data			
Description of release source:	Air toxic compounds emitted from vehicles in Bangkok, Thailand			
Release quantity:	Formaldehyde is emitted by on-road vehicles and non-road equipment. Air toxic emission inventories are estimated according to vehicle fleet distribution, average travel distances per year, and developed emission factors. Taxis have the highest emission factors for formaldehyde. Annual emission amount of formaldehyde is mostly contributed by passenger cars, motorcycles and taxis. Emission inventory of formaldehyde is increased from 8,288 tons/year in 2009 to 11,772 tons/year in 2024. Normally, the highest ambient concentrations of formaldehyde were found at urban roadside sites. It appears that summer photochemical activity contributes more formaldehyde to ambient air than direct vehicle emissions do, as strong seasonal effects are observed.

EXTRACTION

Parameter	Data
Description of release source:	Waste treatment process described in Figure 1. In the presence of catalyst hydrochloric acid, addition condensation reaction was taken place in phenol and formaldehyde. Heating circumfluence made the phenol and formalin in the wastewater condensed into resins completely. In this stage, not only recovered the useful substances in the wastewater, but also reduced the pressure in the subsequent treatment. Then a small amount of phenols, aldehydes, alcohols and other organic matters in the wastewater could be oxidized and decomposed effectively by fenton oxidation in oxidation reactor. Finally, coal fly ash adsorption could further remove COD, phenol and chroma in wastewater, and sand filter could remove fine free fly ash in the wastewater. The final effluent quality could reach the required standard after this combination process. Wastewater in phenolic resin plant were collected into a tank, then pumped into the secondary condensation cauldron, added hydrochloric acid to adjust pH value between 1 and 2. Hydrochloric acid was catalyst of the condensation reaction of phenol and aldehyde. The reaction lasted for 3 hours in the boiling wasterwater with steam heating circumfluence. In the presence of catalyst under acid condition, phenolic resin was synthesized with phenol and formaldehyde in the wastewater. After standing for 15 minutes, resin was released from the bottoms of cauldron. Then did it second time to ensure that the condensation reaction was carried out completely to get more resins and remove more phenol and formaldehyd in the wastewater. The concentration of phenol <300mg/L, COD<1 000 mg/L in the effluent of condensation cauldron. After secondary condensation, the wastewater was bumped to the oxidation reactor, adjusted the pH value of water about 3 in the reactor. Added Fenton reagent to the reactor, hydroxyl radical has the advantages of strong oxidation, rapidly reaction, so phenol, formaldehyde, methanol et al organic matter in the water can be oxidized and decomposed effectively(oxidation reaction temperature is about 50°C, stirring 30min~60min until the wastewater color was light yellow). Then adjusted pH value of the water to neutral using alkali liquor (or limewater), filtered the precipitate in the reactor. Then wastewater was upgraded to the adsorption tower which was filled with coal fly ash. After 60 minutes' absorption in the tower, the concentration of phenol in the effluent was less than 0.5mg/L. Then the effluent water was pumped to a sand filter through a middle tank, in which fine fly ash and other suspended solids in the water were retained. The water flowed into clean water tank upon itself gravity. If the effluent quality deteriorated after the sand filter, backwashed the sand filter using centrifugal pump in the clean water tank. Ensure that the effluent water quality can meet the discharge standard. List of major equipment and structures provided in Table 2.Release comes from wastewater from phenolic resin production containing high concentrations of phenol and formaldehyde. The main raw material for the production of phenolic resin is phenols (phenol, xylene), formaldehyde, ammonia and methanol et al. Usually, producing 1 ton of phenolic resin generated 0.9m3 of high strength acid organic wastewater. The wastewater not only contains large amounts of phenol and free formaldehyde, but also contains methanol and low molecular weight resin.
Release quantity:	Influent water quality had 13300~15100 mg/L and have a discharge standard of <=1.0 mg/L.
Waste treatment methods and pollution control:	Waste treatment methods and pollution control

Study Citation:	Petersen, H. (1987). Formaldehyde and new concepts for its application in textile finishing. Colourage 34(12):23-32.			
HERO ID:	5946609			
Conditions of Use:	commercial use (textile finishing)			
EXTRACTION				
Parameter	Data			
Description of release source:	Formaldehyde liberated by partial hydrolysis on finished textiles			
Release quantity:	For the formaldehyde liberation according to Law 112 are: 350 ppm at 173 deg C, 400 at 160 deg C, 450 at 148 deg C, and 500 ppm at 136 deg C a catalyst ratio of 100 g/I of Fixapret CPN and a curing time of 5 minutes. As the catalyst ratio in the regression equation is not contained as a significant term, the isograms run parallel to the catalyst axis. At temperatures above 150” C, when 100 g/I of crosslinking agent was used with a curing time of 5 minutes with 5 to 50 % of magnesium chloride hexahydrate, the formaldehyde liberation according to Law 112 was less than 450 ppm. For formaldehyde liberation of 550 ppm at a temperature of above 150 deg C, the curing time can be 2 min; at a curing time of 6 min, the same formaldehyde liberation was achieved at a temperature of only approximately 135 deg C. For the various levels of formaldehyde liberation, there is a strong temperature time influence; this applies to Fixapret COC as well as to Fixapret CPN.

Study Citation:	Petinarakis, J.H., Kavvouras, P.K. (2006). Technological factors affecting the emission of formaldehyde from particleboards. Wood Research 51(1):31-40.		
HERO ID:	5946610		
Conditions of Use:	emissions		
EXTRACTION			
Parameter	Data		
Description of release source:	Emission of formaldehyde from particleboards produced from low formaldehyde emission (E1 type) adhesive		
Release quantity:	Emission of formaldehyde increases with the moisture content of the wood-glue mixture before entering the press, decreases with the density of the products, and the temperature of the press, within certain limits, reduces emission. For moisture content of 8% and board density of 700 kg/m3, formaldehyde emission decreases from 15.52 to 12.23 mg/kg when pressing temperature increases from 160 to 190 deg C. Similarly, for moisture content of 14% and board density of 700 kg/m3, formaldehyde emission decreases from 18.27 to 12.35 mg/kg when pressing temperature increases from 160 to 190 deg C. The authors studied the following moisture contents: 8, 10, 12, and 14 percents. Also, 3 pressing temperatures were studied – 160, 175, and 190 deg C. For moisture content of 8% and pressing temperature of 160 deg C, formaldehyde emission decreases from 15.52 to 12.2 mg/kg when board density increases from 700 to 800 kg/m3. Similarly, for moisture content of 14% and pressing temperature of 160 deg C, formaldehyde emission decreases from 18.27 to 12.86 mg/kg when board density increases from 700 to 800 kg/m3. For this study, 3 board densities were studied – 700, 750, and 800 kg/m3. For board density of 700 kg/m3 and pressing temperature of 160 deg C, the formaldehyde emissions increases from 15.52 mg/kg to 18.27 mg/kg when the moisture content increases from 8% to 14%.

Overall Quality Determination		Medium	

Study Citation:	programs, E.O. (1974). Air pollution control engineering and cost study of the paint and varnish industry.			
HERO ID:	6580284			
Conditions of Use:	release			
EXTRACTION				
Parameter	Data			
Description of release source:	There are two major types of emissions from a paint plant. These are confined (or non-fugitive) and fugitive. Fugitive emissions can be pigment particulates and paint solvents. Solvent emission can occur during thinning, filtering, grinding, dispersion, and packaging. Fugitive emissions can also happen from tanks. The number of regulated emissions emanating from a paint plant will vary significantly with the type of operation involved. Some trade sales plants that manufacture none of their own resins and make no effort to confine solvent losses during dispersion, filtering, or storage, will have no non-fugitive emissions. On the other hand, resin plants or paint plants producing resins and varnishes are likely to have a number of non-fugitive emissions. These emissions consist primarily of organic vapors in air or inert gas streams. Major sources included varnish cooking, resin cooking, and thinning. Minor sources include handling and storage, milling, blending and finishing, and filling.			
Release quantity:	Though total emissions from pain plant and resin plant are provided, no information is provided regarding formaldehyde emissions from these plants.			
Release or emission factors:	Release or emission factors			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control

Study Citation:	Rosca, I., Tanczos, I., Schmidt, H. (2004). Formaldehyde emissions from wood-melamine-formaldehyde resin compounds during the extrusion process.			
HERO ID:	5941518			
Conditions of Use:	Resin in wood product manufacturing			
EXTRACTION				
Parameter	Data			
Description of release source:	Formaldehyde emissions during extrusion or compression-moulding process.			
Release or emission factors:	Release or emission factors			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	Medium	Unclear if peer reviewed by appears to contain high quality data.
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	Data is for Austria, an OECD country.
	Metric 3:	Applicability	High	Data is applicable to use of FA resins in wood products.
	Metric 4:	Temporal Representativeness	Low	Data is over 10 years old (2004).
	Metric 5:	Sample Size	Medium	Characterized by range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Includes release source, the operation and emission factors.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Addresses variability (different initial moisture) but does not address uncertainty.
Overall Quality Determination		Medium		

Study Citation:	Saffari, M. (2011). Effects of hardener type and particles size on formaldehyde emission pollution. 8:242-244.		
HERO ID:	5946626		
Conditions of Use:	Use of Resin in Particleboards		
EXTRACTION			
Parameter	Data		
Description of release source:	Release by emission from particleboards.		
Release or emission factors:	Release or emission factors		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	Medium	The release data methodology is known or expected to be accurate but may not cover all release sources at the site.
Domain 2: Representativeness	Metric 2: Geographic Scope	Low	The data are from a non-OECD country (Iran), and locality-specific factors may impact (e.g., potentially greater differences in regulatory emission limits, industry/ process technologies) releases relative to the U.S.
	Metric 3: Applicability	High	The release data are for an occupational scenario within the scope of the risk evaluation.
	Metric 4: Temporal Representativeness	High	The operations, equipment, and worker activities associated with the data indicate that the data should to be representative of current operations, equipment, and activities. The release data were collected after the most recent federal regulatory action (e.g., NE-SHAP for air release or effluent limit guideline (ELG) for water release) or update or are no more than 10 years old, whichever is shorter. If no federal regulation is established, the data are generally no more than 10 years old.
	Metric 5: Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics. It is unclear if analysis is representative.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	Release data include all associated metadata, including release media; process, unit operation, or activity that is the source of the release; and release frequency.
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	High	The release data study addresses variability in the determinants of release. The release data study addresses uncertainty in the release results.
Overall Quality Determination		High

EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1: Methodology	High	The release data methodology is known or expected to be accurate. Aldehyde samples were collected from the dilution tunnel through a heated (110°C) sample line using dinitrophenyl hydrazine (DNPH)-coated silica gel cartridges that were subsequently analyzed by high performance liquid chromatography.	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	US	
	Metric 3: Applicability	High	The release data are for on road vehicles which is an occupational scenario within the scope of the risk evaluation.	
	Metric 4: Temporal Representativeness	Low	Provided data may represent outdated operations, equipment, and activities compared to current operations, equipment, and worker activities. The data were published in 1989, before the most recent PEL (1992) and are more than 20 years old.	
	Metric 5: Sample Size	Medium	aggregated emission factors were provided two fuels (gasoline and M85) and three emission points (tailpipe, evaporative, refueling) plus an aggregated factor.	
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	N/A	N/A - This metric is not applicable to the data being extracted	
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Low	The release data study does not address variability or uncertainty.	
Overall Quality Determination		Medium

HERO ID:	3259673			
Conditions of Use:	Multiple			
EXTRACTION				
Parameter		Data		
Description of release source:		Primary contributors are mobile sources to ambient levels of toxic VOCs at urban locations across Canada. The large secondary contribution for formaldehyde is likely coming from the oxidation of biogenic emissions, in particular, isoprene OH-oxidation which forms formaldehyde at high gas-phase yield.		
Release quantity:		As per 2006 Canadian NPRI, emission of formaldehyde amount to 33 kilotons/yr. Formaldehyde emissions declined marginally from 2004 to 2010 for the average of all 15 sites monitored. The summertime and wintertime average observed formaldehyde are 2.4 ± 1.1 ppbv and 1.14 ± 0.73 ppbv. Primary mobile emissions contribute 19 % and 10% to formaldehyde and acetaldehyde in Edmonton in the summer. In the summer, primary mobile emissions are 12 % and 6 % for formaldehyde and acetaldehyde in Toronto, while area/point formaldehyde emissions are 17 % and 9 %.		
Release frequency:		varying releases during weekday and weekend		
EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	release data methodology is known
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	data are from an OECD country other than the U.S
	Metric 3:	Applicability	High	release data are for an occupational scenario within the scope of the risk evaluation
	Metric 4:	Temporal Representativeness	Medium	data is between 10 and 20 years old
	Metric 5:	Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Low	Release data include release media but no other metadata
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	The release data study does not address variability or uncertainty.

EXTRACTION				
Parameter	Data			
Description of release source:	vehicle exhaust			
Release or emission factors:	Release or emission factors			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1: Methodology	High	The release data methodology is known; a constant volume sample system was used and aldehyde analyses were done using liquid chromatographic procedures.	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	US	
	Metric 3: Applicability	High	The release data are for vehicle exhaust an occupational scenario within the scope of the risk evaluation.	
	Metric 4: Temporal Representativeness	Low	Provided data may represent outdated operations, equipment, and activities compared to current operations, equipment, and worker activities. The data were published in 1992, around the time of the most recent PEL (1992) but more than 20 years old.	
	Metric 5: Sample Size	Medium	Distribution of samples is characterized by an average value for fuel injection vehicles including standard deviation. The vehicle equipped with a carburetor only had an average value. Uncertainty statistics were not provided. It is unclear if this analysis is representative given the age of the vehicles included in the study.	
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Release data include most critical metadata, including release media and release frequency, but lacks additional metadata, such as process, unit operation, and/or activity that is the source of the release	
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	High	the data provided were derived from 7 vehicles with different cylinder displacement, number of cylinders and whether equipped with fuel injectors or carburetors manufactured between 1986 to 1990, which is useful in evaluating variability. Uncertainty was assumed to be addressed in the analysis methodology.	
Overall Quality Determination		High

Overall Quality Determination			High	

Study Citation:	Tohmura, S. I., Miyamoto, K., Inoue, A. (2015). Effects of Ethanol-Supplemented Phenol-Resorcinol-Formaldehyde Resin on Formaldehyde and Acetaldehyde Emissions from Glued-Laminated Timbers. Forest Products Journal 65(1-2):31-37.		
HERO ID:	2895587		
Conditions of Use:	Compressed Wood Product Manufacturing		
EXTRACTION			
Parameter	Data		
Description of release source:	Emissions from glued-laminated timbers bonded with phenol-resorcinol-formaldehyde resin adhesives, some of which included ethanol as a solvent.		
Release quantity:	GLA through GLB were glue-laminated timber for which PRF resin of company A through D were used. Formaldehyde emissions from GLB and GLD specimens were initially 680 and 583 ug/m2/h, respectively; they rapidly decreased to below 100 ug/m2/h within 3 weeks. This was probably because the formaldehyde emissions were trapped immediately following production by wrapping the timber specimens. Formaldehyde emissions from GLA and GLC specimens behaved nearly the same as that from the GLS specimen (control – prepared without application of an adhesive). Emissions from GLA and GLC were less than 100 ug/m2/h initially and decreased to less than 10 ug/m2/h within a week. The observed differences in the two classes of emission levels might be related to the curing rate. In the effect of ethanol content of PRF resin experiment, formaldehyde emission rates varied from 10 to 25 ug/m2/h in the early stages of the experiment, they decreased within a week. No relationship between the orientation of the exposed wood surfaces of the glued-laminated timbers and formaldehyde emission was observed.

Study Citation:	U.S. EPA, (1999). Flexographic printing - generic scenario for estimating occupational exposures and environmental releases: Draft.			
HERO ID:	6385709			
Conditions of Use:	commercial use: chemical substances in packaging, paper, plastics and hobby products.			
EXTRACTION				
Parameter	Data			
Description of release source:	This scenario examines the environmental releases that occur during makeready and during the actual production run of the flexographic press. The only releases discussed in this study are air releases, although the only expected significant water releases would be from potential rinsing of spent containers or from equipment cleaning if these wastes are not recycled or collected for incineration as expected.Environmental release quantities depend on many variables, including the volatile content of the ink mixture, whether exhaust streams contain air control devices, the ink consumption rates, and whether the ink was mixed with additives prior to use.			
Release or emission factors:	Release or emission factors			
Release frequency:	Facilities are expected to operate 300 days per year			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
Comments:	Note, formaldehyde is not specifically mentioned in the report, but the provided data are relevant to account for process and operational assumptions.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	The release data methodology is known or expected to be accurate and is known to cover all release sources at the site.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	USA
	Metric 3:	Applicability	Medium	The release data are for an occupational scenario within the scope of the risk evaluation, but no formaldehyde specific information.
	Metric 4:	Temporal Representativeness	Low	The data are more than 20 years old (1999)
	Metric 5:	Sample Size	Low	Data/parameters characterized by no statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	Release data include all associated metadata, including release media; process, unit process, activity that is the source of the release; and release frequency.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	The release data study provides only limited discussion of the variability in the determinants of release. The release data study provides only limited discussion of the uncertainty in the release results.
Overall Quality Determination		Medium		

Study Citation:	U.S. EPA, (2019). National Emissions Inventory (NEI) [database]: CASRNs 79-00-5, 75-34-3, 107-06-2, 78-87-5, 84-61-7, 106-99-0, 106-93-4, 50-00-0, 85-44-9, 106-46-7, 85-68-7, 84-74-2, and 115-86-6.			
HERO ID:	6535959			
Conditions of Use:	All			
EXTRACTION				
Parameter	Data			
Description of release source:	Provides unit/process of release.			
Release or emission factors:	Release or emission factors			
Release frequency:	Provides annual operating time for some submissions			
Waste treatment methods and pollution control:	nan			
Comments:	Large dataset of facilities and reported formaldehyde emissions spanning across multiple COUs.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	Medium	Submitters provide general method used to calculate emissions, but details not provided.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	NEI is U.S. based data
	Metric 3:	Applicability	High	NEI includes industries included in the scopes of the risk evaluation
	Metric 4:	Temporal Representativeness	High	NEI data are from 2017, less than 10 years old.
	Metric 5:	Sample Size	Medium	Dataset is limited to units subject to NESHAP with threshold potential to emit, although states may have different requirements; statistical representativeness is unclear.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	NEI includes release media and generally also includes daily and annual operating time, specific unit/process that is the source of release, and presence of engineering controls.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	NEI does not address variability or uncertainty in submitter provided data.
Overall Quality Determination			High

Conditions of Use:	Pharmaceutical Production (6.13)			
EXTRACTION				
Parameter	Data			
Description of release source:	escaped solvents from dryers, reactors, distillation systems, and storage tanks			
Release quantity:	Provides table of annual amounts of solvents (Mg) purchased by U.S. pharmaceutical companies and ultimate disposition (in % of purchased solvent). Multiply the values together to calculate releases by media.			
Release or emission factors:	Release or emission factors			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	Medium	Methodology is known and expected to be accurate but cover only air release sources at the site.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	AP-42 is based on U.S. data
	Metric 3:	Applicability	Medium	The release data are for an occupational scenario that is similar to an occupational scenario within the scope of the risk evaluation, in terms of the type of industry, operations, and work activities.
	Metric 4:	Temporal Representativeness	Low	Assessment is based on data greater than 20 years old and older than the latest NESHAP for the Pharmaceuticals Production Industry.
	Metric 5:	Sample Size	High	Statistical distribution of samples is fully characterized (discrete release percentages and quantities provided).
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Release media, quantity, controls,and emission factors provided but missing release frequency.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	High	Uncertainty is addressed by explaining how control efficiency and disposal methods are highly dependent on individual processes. Variability addressed by listing release information for many different solvents and based on data from 26 sites.
Overall Quality Determination			Medium	

Study Citation:	U.S. EPA, (1995). Chapter 4.2: Introduction to surface coating. Compilation of air pollutant emission factors. Volume I: Stationary point and area sources, fifth edition, AP-42.
HERO ID:	7315820
Conditions of Use:	Application of paints and coatings (4.2.1)

EXTRACTION

Parameter	Data
Description of release source:	Coating an architectural surface or automobile refinishing. Architectural surface coating is considered to involve both industrial and nonindustrial structures. Automobile refinishing pertains to the painting of damaged or worn highway vehicle finishes and not to the painting of vehicles during manufacture.
Release quantity:	Table 4.2.1-1 National Emissions and Emission factor-Emission factors based on national emissions dataPer Capita(given in kg/yr and g/day)"Architectural Surface Coating - 5.8 g nonmethane VOC/dayAutomobile Refinishing - 2.7 g nonmethane VOC/day"Per employee"Architectural Surface Coating - 2.09 kg nonmethane VOC/person/yrAutomobile Refinishing - 0.84 kg nonmethane VOC/person/yr"
Release frequency:	365 for architectural, 312 for automobile refinishing
Waste treatment methods and pollution control:	Waste treatment methods and pollution control
Comments:	Chapter 4.2.1 Nonindustrial Surface Coating

EVALUATION

Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	Methodology is known and expected to be accurate and cover all release sources at the site.

HERO ID:	7315820			
Conditions of Use:	Application of paints and coatings (4.2.2.6)			
EXTRACTION				
Parameter	Data			
Description of release source:	The main emission points from paper coating lines are the coating applicator and the oven (see Figure 4.2.2.6-1). In a typical paper-coating plant, about 70 percent of all solvents used are emitted from the coating lines, with most coming from the first zone of the oven. The other 30 percent are emitted from solvent transfer, storage, and mixing operations and can be reduced through good housekeeping practices. All solvent used and not recovered or destroyed can be considered potential emissions.

EXTRACTION**Parameter****Data**

Description of release source:

Evaporative emissions from the transportation and marketing of petroleum liquids may be considered, by storage equipment and mode of transportation used, in four categories: 1. Rail tank cars, tank trucks, and marine vessels: loading, transit, and ballasting losses. 2. Service stations: bulk fuel drop losses and underground tank breathing losses. 3. Motor vehicle tanks: refueling losses. 4. Large storage tanks: breathing, working, and standing storage losses. Loading losses are the primary source of evaporative emissions from rail tank car, tank truck, and marine vessel operations. Loading losses occur as organic vapors in "empty" cargo tanks are displaced to the atmosphere by the liquid being loaded into the tanks. These vapors are a composite of (1) vapors formed in the empty tank by evaporation of residual product from previous loads, (2) vapors transferred to the tank in vapor balance systems as product is being unloaded, and (3) vapors generated in the tank as the new product is being loaded. The quantity of evaporative losses from loading operations is, therefore, a function of the following parameters: - Physical and chemical characteristics of the previous cargo; - Method of unloading the previous cargo; - Operations to transport the empty carrier to a loading terminal; - Method of loading the new cargo; and - Physical and chemical characteristics of the new cargo. In the splash loading method, the fill pipe dispensing the cargo is lowered only part way into the cargo tank. Significant turbulence and vapor/liquid contact occur during the splash liquid droplets will be entrained in the vented vapors. A second method of loading is submerged loading. Two types are the submerged fill pipe method and the bottom loading method. In the submerged fill pipe method, the fill pipe extends almost to the bottom of the cargo tank. In the bottom loading method, a permanent fill pipe is attached to the cargo tank bottom. During most of submerged loading by both methods, the fill pipe opening is below the liquid surface level. Liquid turbulence is controlled significantly during submerged loading, resulting in much lower vapor generation than encountered during splash loading. The recent loading history of a cargo carrier is just as important a factor in loading losses as the method of loading. If the carrier has carried a nonvolatile liquid such as fuel oil, or has just been cleaned, it will contain vapor-free air. If it has just carried gasoline and has not been vented, the air in the carrier tank will contain volatile organic vapors, which will be expelled during the loading operation along with newly generated vapors. Cargo carriers are sometimes designated to transport only one product, and in such cases are practicing "dedicated service". Dedicated gasoline cargo tanks return to a loading terminal containing air fully or partially saturated with vapor from the previous load. Cargo tanks may also be "switch loaded" with various products, so that a nonvolatile product being loaded may expel the vapors remaining from a previous load of a volatile product such as gasoline. These circumstances vary with the type of cargo tank and with the ownership of the carrier, the petroleum liquids being transported, geographic location, and season of the year. Ballasting losses are a major source of evaporative emissions associated with the unloading of petroleum liquids at marine terminals. It is common practice to load several cargo tank compartments with sea water after the cargo has been unloaded. This water, termed "ballast", improves the stability of the empty tanker during the subsequent voyage. Although ballasting practices vary, individual cargo tanks are ballasted typically about 80 percent, and the total vessel 15 to 40 percent, of capacity. Ballasting emissions occur as vapor-laden air in the "empty" cargo tank is displaced to the atmosphere by ballast water being pumped into the tank. Upon arrival at a loading port, the ballast water is pumped from the cargo tanks before the new cargo is loaded. The ballasting of cargo tanks reduces the quantity of vapors returning in the empty tank, thereby reducing the quantity of vapors emitted during subsequent tanker loading. Regulations administered by the U. S. Coast Guard require that, at marine terminals located in ozone nonattainment areas, large tankers with crude oil washing systems contain the organic vapors from ballasting. This is accomplished principally by displacing the vapors during ballasting into a cargo tank being simultaneously unloaded. In other areas, marine vessels emit organic vapors directly to the atmosphere. In addition to loading and ballasting losses, losses occur while the cargo is in transit. Transit losses are similar in many ways to breathing losses associated with petroleum storage. Emissions from gasoline truck cargo tanks during transit depend on the extent of venting from the cargo tank during transit, which in turn depends on the vapor tightness of the tank, the pressure relief valve settings, the pressure in the tank at the start of the trip, the vapor pressure of the fuel being transported, and the degree of fuel vapor saturation of the space in the tank. The emissions are not directly proportional to the time spent in transit. If the vapor leakage rate of the tank increases, emissions increase up to a point, and then the rate changes as other determining factors take over. Truck tanks in dedicated vapor balance service usually contain saturated vapors, and this leads to lower emissions during transit because no additional fuel evaporates to raise the pressure in the tank to cause venting. Service Stations - Another major source of evaporative emissions is the filling of underground gasoline storage tanks at service stations. Gasoline is usually delivered to service stations in 30,000-liter (8,000-gal) tank trucks or smaller account trucks. Emissions are generated when gasoline vapors in the underground storage tank are displaced to the atmosphere by the gasoline being loaded into the tank. As with other loading losses, the quantity of loss in service station tank filling depends on several variables, including the method and rate of filling, the tank configuration, and the gasoline temperature, vapor pressure and composition. A second source of vapor emissions from service stations is underground tank breathing. Breathing losses occur daily and are attributable to gasoline evaporation and barometric pressure changes. The frequency with which gasoline is withdrawn from the tank, allowing fresh air to enter to enhance evaporation, also has a major effect on the quantity of these emissions. An average breathing emission rate is 120 mg/L (1.0 lb/1000 gal) of throughput.

EXTRACTION**Parameter****Data**

Description of release source:

Air emissions from catalytic cracking processes are (1) combustion products from process heaters and (2) flue gas from catalyst regeneration. Emissions from process heaters are discussed below. Emissions from the catalyst regenerator include hydrocarbons, oxides of sulfur, ammonia, aldehydes, oxides of nitrogen, cyanides, carbon monoxide (CO), and particulates. The particulate emissions from FCC units are much greater than those from TCC units because of the higher catalyst circulation rates used. FCC particulate emissions are controlled by cyclones and/or electrostatic precipitators or wet scrubbers. Particulate control efficiencies are as high as 80 to 85 percent.^{3,5} Carbon monoxide waste heat boilers reduce the CO and hydrocarbon emissions from FCC units to negligible levels.³ TCC catalyst regeneration produces similar pollutants to FCC units, but in much smaller quantities. The particulate emissions from a TCC unit are normally controlled by high-efficiency cyclones. Carbon monoxide and hydrocarbon emissions from a TCC unit are incinerated to negligible levels by passing the flue gases through a process heater firebox or smoke plume burner. In some installations, sulfur oxides are removed by passing the regenerator flue gases through a water or caustic scrubber. The major source of emissions from compressor engines is combustion products in the exhaust gas. These emissions include CO, hydrocarbons, nitrogen oxides, aldehydes, and ammonia. Sulfur oxides may also be present, depending on the sulfur content of the natural gas. All these emissions are significantly higher in exhaust from reciprocating engines than from turbine engines. The major emission control technique applied to compressor engines is carburetion adjustment similar to that applied on automobiles. Catalyst systems similar to those of automobiles may also be effective in reducing emissions, but their use has not been reported. Fugitive emission sources include leaks of hydrocarbon vapors from process equipment and evaporation of hydrocarbons from open areas, rather than through a stack or vent. Fugitive emission sources include valves of all types, flanges, pump and compressor seals, process drains, cooling towers, and oil/water separators. Fugitive emissions are attributable to the evaporation of leaked or spilled petroleum liquids and gases. Normally, control of fugitive emissions involves minimizing leaks and spills through equipment changes, procedure changes, and improved monitoring, housekeeping, and maintenance practices. - Oil/water separators (waste water treatment). All refineries employ some form of waste water treatment so water effluents can safely be returned to the environment or reused in the refinery. The design of waste water treatment plants is complicated by the diversity of refinery pollutants, including oil, phenols, sulfides, dissolved solids, and toxic chemicals. Although the treatment processes employed by refineries vary greatly, they generally include neutralizers, oil/water separators, settling chambers, clarifiers, dissolved air flotation systems, coagulators, aerated lagoons, and activated sludge ponds. Refinery water effluents are collected from various processing units and are conveyed through sewers and ditches to the treatment plant. Most of the treatment occurs in open ponds and tanks. The main components of atmospheric emissions from waste water treatment plants are fugitive VOCs and dissolved gases that evaporate from the surfaces of waste water residing in open process drains, separators, and ponds. Treatment processes that involve extensive contact of waste water and air, such as aeration ponds and dissolved air flotation, have an even greater potential for atmospheric emissions. Section 4.3, "Waste Water Collection, Treatment And Storage", discusses estimation techniques for such water treatment operations. The control of waste water treatment plant emissions involves covering systems where emission generation is greatest (such as oil/water separators and settling basins) and removing dissolved gases from water streams with sour water strippers and phenol recovery units before their contact with the atmosphere. These control techniques potentially can achieve greater than 90 percent reduction of wastewater system emissions- Storage. All refineries have a feedstock and product storage area, termed a "tank farm", which provides surge storage capacity to ensure smooth, uninterrupted refinery operations. Individual storage tank capacities range from less than 160 m³ to more than 79,500 m³ (1,000 to 500,000 bbl). - Transfer operations; although most refinery feedstocks and products are transported by pipeline, some are transported by trucks, rail cars, and marine vessels. They are transferred to and from these transport vehicles in the refinery tank farm area by specialized pumps and piping systems. - Cooling towers are used extensively in refinery cooling water systems to transfer waste heat from the cooling water to the atmosphere. The only refineries not employing cooling towers are those with once-through cooling. The increasing scarcity of a large water supply required for once-through cooling is contributing to the disappearance of that form of refinery cooling. In the cooling tower, warm cooling water returning from refinery processes is contacted with air by cascading through packing. Cooling water circulation rates for refineries commonly range from 7 to 70 L/minute per m³/day (0.3 to 3.0 gal/minute per bbl/day) of refinery capacity. Atmospheric emissions from the cooling tower consist of fugitive VOCs and gases stripped from the cooling water as the air and water come into contact. These contaminants enter the cooling water system from leaking heat exchangers and condensers. Control of cooling tower emissions is accomplished by reducing contamination of cooling water through the proper maintenance of heat exchangers and condensers. The effectiveness of cooling tower controls is highly variable, depending on refinery configuration and existing maintenance practices.

Overall Quality Determination		High		

Study Citation:	Wang, W. L., Gardner, D. J., Baumann, D., M.G. (1999). Volatile organic compound hot-press emissions from southern pine furnish as a function of adhesive type.			
HERO ID:	5937853			
Conditions of Use:	Incorporation into Article-Wood Product Manufacturing (Resins)			
EXTRACTION				
Parameter	Data			
Description of release source:	Formaldehyde hot-pressing emissions from Southern Pine panels come from two main sources: free formaldehyde in the adhesives and emissions from the wood furnish itself. Two of the three predominant adhesives, UF and PF resins, contain free formaldehyde but the third, pMDI, does not. A portion of the free formaldehyde in UF and PF will be emitted from the mat during hot pressing, and the amount of formaldehyde emitted is affected by the press conditions. Appropriate press conditions are determined by the physical and chemical properties of the adhesive, such as curing rate and curing temperature.			
Release quantity:	Formaldehyde emissions during hot-pressing of panels with UF resin ranged from 80.05 to 445.98 mg per kg oven-dried board (mg/kg OD board), which was significantly higher than emissions from panels pressed with either PF or pMDI resin. Emissions from panels pressed with pMDI ranged from 0.10 to 60.11 mg/kg OD board and with PF ranged from 8.79 to 16.20 mg/kg OD board. The UF resins are known to contain higher levels of free formaldehyde and are subject to hydrolysis, releasing formaldehyde, so the higher levels of formaldehyde emissions for this resin were expected. For panels bonded with PF and pMDI under similar conditions, the PF panels emitted significantly less formaldehyde than pMDI panels. Furnish pressed at the center level press variables with pMDI and with no resin exhibited emission levels of 33.07 and 41.10 mg/kg OD board, respectively. Thus, formaldehyde was emitted from the wood furnish alone and application of the pMDI resin reduced emissions by approximately 20 percent. However, panels bonded with PF resin showed even greater reductions relative to furnish pressed with no resin. At the center point of the press variables, formaldehyde emissions from particles with PF resin were 11.91 mg/kg OD board, which were also much lower than from the neat wood particles, 71.33 mg/kg OD board, a reduction by approximately 70 percent.

Description of release source:	Emissions from a direct-injection diesel engine fueled with diesel, B20 (20% biodiesel on volume basis), B50, B75 and biodiesel.
Release quantity:	Brake specific formaldehyde emissions increase with increasing biodiesel concentration in the tested fuels. By conducting Student's t-test, there are no significant differences for the weighted brake specific formaldehyde emissions between diesel and B20 and among B50, B75 and biodiesel; however, significant increases are observed between biodiesel and diesel and between biodiesel and B20. The weighted brake specific formaldehyde emissions exhibit very high correlation coefficients (0.93 for weighted brake specific formaldehyde) with the biodiesel concentration which indicate that the weighted brake specific carbonyl compound emissions are proportional to the biodiesel content.
Release or emission factors:	Release or emission factors
Waste treatment methods and pollution control:	Waste treatment methods and pollution control

EVALUATION				
Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	The release data methodology is expected to be accurate
Domain 2: Representativeness	Metric 2:	Geographic Scope	Low	The data are from a non-OECD country
	Metric 3:	Applicability	Medium	The release data are for an occupational scenario that is similar to an occupational scenario within the scope of the risk evaluation
	Metric 4:	Temporal Representativeness	High	Data is less than 10 years old
	Metric 5:	Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Low	Release data include release media but no other metadata.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	The release data study provides limited discussion on variability but does not address uncertainty.

EXTRACTION				
Parameter	Data			
Release quantity:	97,506 tons for 1990			
Release or emission factors:	Release or emission factors			
Release frequency:	annual (emisson factors were also provided in mg/mi)			
EVALUATION				
Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	testing was performed by NREL at EPA dynamometers using urban driving cycles
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	US
	Metric 3:	Applicability	High	The release data are for mobile sources which is a scenario within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	Low	The report was published in 1999 and is therefore more than 20 years old. Testing was performed in 1998 on vehicles that have a model year ranging from 1992-1995.
	Metric 5:	Sample Size	Medium	Individual emission factors are provided for a limited number of (8) vehicles.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Release data include most critical metadata, including release media and release frequency, but lacks additional metadata, such as process, unit operation, and/or activity that is the source ofthe release
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	The emission factors were provided for individual vehicles with different ages and mileage allow for an approximation of variance. The study did not provide any discussion of the uncertainty in the release results, though it is likely that the NREL methodology accounted for them.

HERO ID:	3455178			
Conditions of Use:	Office Environment			
EXTRACTION				
Parameter	Data			
Description of release source:	Building materials (such as medium density fiberboard)			
Release quantity:	E, which is the steady state emission rate as ug/(m2 h), increases with increase in relative humidity and indoor temperature. As relative humidity increases from 20 to 80 percent, the E increases from approx. 200 to 1200 for an indoor temperature of 25 deg C. As temperature increases from 25 to 50 deg C, the E increases from approx. 60 to 4100 for a relative humidity of 50 percent. The ratio of E in summer to that in winter is about 1.63, and this ratio can be regarded as the ratio of formaldehyde concentration in indoor environment in the two seasons.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	release data methodology is known or expected to be accurate
Domain 2: Representativeness	Metric 2:	Geographic Scope	Low	data are from a non-OECD country

HERO ID:	3073483
Conditions of Use:	Automobile Exhaust

EXTRACTION

Parameter	Data
Description of release source:	Releases come from in use heavy duty diesel trucks (HDDTs) and measured against different emission standards. Emissions varied by different emission standards, with formaldehyde emission increasing with increasingly stringent emission standards. Emissions also were lower on highway HDDTs versus non-highway HDDTs.
Release quantity:	Emissions consisted of 47.9% formaldehyde (out of the total percent of carbonyl compounds)
Release or emission factors:	Release or emission factors
Waste treatment methods and pollution control:	Waste treatment methods and pollution control
Comments:	Note: this only gives the percent of formaldehyde as a function of overall carbonyl content in emissions not as a function of total emissions

EVALUATION

Domain	Metric	Rating	Comments
Domain 1: Reliability			
Metric 1:	Methodology	High	Source is peer reviewed so likely contains high quality data.
Domain 2: Representativeness			
Metric 2:	Geographic Scope	Low	Data is for China, a non-OECD country.
Metric 3:	Applicability	Low	Data is not explicitly for a specific use of formaldehyde, it is just an emission from diesel as a fuel in an engine.
Metric 4:	Temporal Representativeness	High	Data is less than 10 years old (2015)
Metric 5:	Sample Size	Medium	Characterized by a range of data with uncertain statistics.
Domain 3: Accessibility/ Clarity			
Metric 6:	Metadata Completeness	Medium	Provides emission factors, description of release source, concentration of formaldehyde in emissions, and specifies the effect of pollution control devices but does not state what those devices are.
Domain 4: Variability and Uncertainty			
Metric 7:	Metadata Completeness	Low	Addresses variability by showing data from other similar literature sources and the emissions of different engines with different pollution controls. Does not address uncertainty.

Study Citation:	Younesi-Kordkheili, H., Pizzi, A., Niyatzade, G. (2016). Reduction of formaldehyde emission from particleboard by phenolated kraft lignin. Journal of Adhesion 92(6):485-497.
HERO ID:	5953822
Conditions of Use:	emission

EXTRACTION	
Parameter	Data
Description of release source:	Formaldehyde emission from particleboard modified by lignin and phenolated lignin
Release quantity:	Formaldehyde emission differs greatly among the cured resins. It can be observed that if lignin is incorporated into the UF resin, the formaldehyde emission from the panels decreases independently if the lignin component as such is modified or not. Lignin addition, leading to lower F/U ratio, significantly decreases formaldehyde emission from the panels. Formaldehyde emission from manufactured particleboards made from synthesized resins are: 4.3 mg/(100g oven dry basis) with lignin content 0%; 3.5 mg/(100g oven dry basis) for LUF and 3.2 mg/(100g oven dry basis) for PLUF with lignin content 10%; 3.4 mg/(100g oven dry basis) for LUF and 2.9 mg/(100g oven dry basis) for PLUF with lignin content 15%; 3.1 mg/(100g oven dry basis) for LUF and 2.6 mg/(100g oven dry basis) for PLUF with lignin content 20%. The results also indicate that the panels made from PLUF resins exhibited lower formaldehyde emission than those made from LUF and UF resins, respectively.

Domain 1: Reliability	Metric 1: Methodology	Medium	Methodology is known and expected to be accurate but may not cover all release sources at the site.	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	Data are from the U.S.	
	Metric 3: Applicability	High	Data are for use of fuels and related products, an in-scope occupational scenario.	
	Metric 4: Temporal Representativeness	High	Data less than 10 years old.	
	Metric 5: Sample Size	Medium	Sample distribution characterized by limited statistics (range) but discrete samples not provided and distribution not fully characterized.	
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Release data include most critical metadata, including release media and release frequency, but lacks additional metadata, such as process, unit operation, and/or activity that is the source of the release	
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Medium	The release data study provides only limited discussion of the variability in the determinants of release. The release data study provides only limited discussion of the uncertainty in the release results	
Overall Quality Determination		High		

Study Citation:	Zhu, J., Cao, X.L., Pigeon, R., Mitchell, K. (2003). Comparison of vehicle exhaust emissions from modified diesel fuels. Journal of the Air and Waste Management Association 53(1):67-76.			
HERO ID:	39179			
Conditions of Use:	Automobile Exhaust			
EXTRACTION				
Parameter	Data			
Description of release source:	Vehicle Exhaust Emissions			
Release quantity:	Base fuel: cold start 40.4 +/-1.1 mg/mi; hot start 45.0+/-1.2 mg/mi. 2-EHN fuel: cold start 36.4 mg/mi; hot start 36.8 mg/mi. DEDM: cold start 40.9 mg/mi; hot start 37.2 mg/mi.			
Release or emission factors:	Release or emission factors			
EVALUATION				
Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	The methodology is known and expected to be accurate. Samples were collected on Sep-Pak 2,4-dinitrophenylhydrazine (DNPH)-silica cartridges and analyzed using a HPLC instrument using a modified American Society for Testing and Materials (ASTM) Standard Test Method D5197.
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	Canada - OECD member
	Metric 3:	Applicability	High	The release data are for vehicle exhaust which is an occupational scenario within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	Medium	The data were collected after the most recent federal regulatory action but are generally, more than 10 years old and less than 20 years old. However, equipment are expected to be reasonably representative of current conditions.
	Metric 5:	Sample Size	Medium	The statistical distribution of samples is characterized by a margin or error. Because the emission factors were derived from a single 1996 GM Light duty diesel pick up truck, it is uncertain if the data are representative of the current US fleet of light duty diesel trucks.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	N/A	N/A - This metric is not applicable to the data being extracted
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	High	The study provided mean value and the margin of error which could be used to evaluate variability. Uncertainty is accounted for in the methods used to analyze the samples.
Overall Quality Determination			High

Study Citation:	NICNAS, (2006). Priority existing chemical assessment report no. 28 formaldehyde.			
HERO ID:	192040			
Conditions of Use:	All Uses- Emission			
EXTRACTION				
Parameter	Data			
Description of release source:	A wide range of human domestic and industrial activities is responsible for both direct and indirect releases of formaldehyde into the atmosphere from diffuse and point sources. Emission from fuel combustion is perhaps the single most important anthropogenic source of atmospheric formaldehyde, with formaldehyde being released directly or subsequently formed by oxidation of higher alkanes, hydrocarbons, or other precursors, released from combustion processes. Release of formaldehyde into the atmosphere or aquatic environment may also occur during its manufacture, or when used as an intermediate in manufacturing, and during use of products containing formaldehyde. Emissions of formaldehyde to water and soil may be expected to occur via sewage treatment facilities during manufacture of formaldehyde and formaldehyde products and during use of products containing formaldehyde, including consumer products.			
Release quantity:	Recent data from the Australian National Pollution Inventory (NPI) database for emissions of formaldehyde indicate that almost all formaldehyde is released to the atmosphere, with total emissions estimated to be 7150 tonnes for the year 2002-2003 compared with 6600 tonnes for the year 2001-2002. However, formaldehyde emissions to water and soil are significantly less than emissions to the air. Emissions data from the NPI indicate only about 1000 kg of formaldehyde was released into water and/or onto land from point sources in the reporting year 2001-2002 and only 5 kg in 2002-2003. No distinction was made between amounts released to soil and that to water.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	report uses high quality data
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	The data are from an OECD country other than the U.S
	Metric 3:	Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	Medium	The report is generally more than 10 years but no more than 20 years old.
	Metric 5:	Sample Size	Low	characterized by no statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	report clearly documents its data sources
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	The report does not address variability or uncertainty.
Overall Quality Determination		Medium		

Study Citation:	NICNAS, (2006). Priority existing chemical assessment report no. 28 formaldehyde.		
HERO ID:	192040		
Conditions of Use:	Incorporation into Article- Wood Product Manufacturing		
EXTRACTION			
Parameter	Data		
Description of release source:	Emissions of formaldehyde from the wood and paper industries are expected to occur mainly through fugitive and point source emissions of vapours from process and storage areas, and with some emissions of formaldehyde from combustion activities. The processes emitting vapours will differ with the type of industry, but may include gluing and veneering, steam heating, wood preservation treatment, and drying activities. Combustion sources include wood and paper drying, incinerating, and boiler operations.		
Release quantity:	The average emission rates were 8195 and 7061 kg/year for the 2001- 2002 and 2002-2003 reporting years, respectively, with a maximum of 51,844 kg/year (2002-2003 data) for an individual wood products activity		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	report uses high quality data, cited as national pollution inventory, which is a governmental source on emissions.
Domain 2: Representativeness	Metric 2: Geographic Scope	Medium	The data are from an OECD country other than the U.S
	Metric 3: Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.
	Metric 4: Temporal Representativeness	Medium	The report is generally more than 10 years but no more than 20 years old.
	Metric 5: Sample Size	N/A	Values are an aggregated value of the reported emissions, no statistics (e.g., mean, range)
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	report clearly documents its data sources and assumptions
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Medium	The assessment provides only limited discussion of the uncertainty in the results. Variability is discussed in relation to the sources of the emissions.
Overall Quality Determination		High	

Study Citation:	NICNAS, (2006). Priority existing chemical assessment report no. 28 formaldehyde.			
HERO ID:	192040			
Conditions of Use:	Other Use- Emissions from Mining			
EXTRACTION				
Parameter	Data			
Description of release source:	Emissions of formaldehyde from mining operations are expected to occur mainly via vehicle exhaust from mining equipment and transport, cleaning and site maintenance activities, power generation using fossil fuels, combustion in boilers, and blasting.			
Release quantity:	Metal ore mining activities (iron, gold, silver-lead, or nickel) contributed the highest emissions, although some facilities in this category reported no emissions of formaldehyde. The average emission rate for mining activities was 12 203 kg/year with a maximum of 401 112 kg/year for a nickel mining activity in Western Australia in the 2001-2002 reporting year. For the 2002-2003 reporting year the average emission rate was 7254 kg/year with a maximum of 363 769 kg/year for an iron mining activity in Western Australia.

EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Methodology is known and expected to be accurate and cover all release sources at the site.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	Data are from the U.S.
	Metric 3:	Applicability	High	Data are for ink, toner, and colorant products, an in-scope occupational scenario.
	Metric 4:	Temporal Representativeness	Low	Data were collected prior to the most recent NESHAPs for air releases.
	Metric 5:	Sample Size	Medium	Sample distribution characterized by limited statistics (mean) but discrete samples not provided and distribution not fully characterized.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Release media and release frequency provided but missing release quantity.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Variability addressed by giving both fugitive and stack emission factors, but uncertainty is not addressed.
Overall Quality Determination		Medium		

Study Citation:	U.S. EPA, (2022). Commercial use of automotive detailing products - Generic scenario for estimating occupational exposures and environmental releases (Methodology review draft).			
HERO ID:	10480464			
Conditions of Use:	Automotive detailing products			
EXTRACTION				
Parameter	Data			
Description of release source:	Container unloading, container cleaning, application and use of automotive detailing products.			
Release or emission factors:	nan			
Release frequency:	260 day/yr			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Assessment uses high quality information/data from frequently-used sources.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	This GS is based on U.S. data.
	Metric 3:	Applicability	Medium	Data is for an in-scope occupational scenario; however, data is general and not specific to a chemical.
	Metric 4:	Temporal Representativeness	High	Assessment is based on current industry conditions and data no more than 10 years old.
	Metric 5:	Sample Size	Medium	Sample distribution characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	All data sources, methods, results, and assumptions are clearly documented.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	Variability and uncertainty are not addressed.
Overall Quality Determination		High		

Study Citation:	U.S. EPA, (2023). Use of laboratory chemicals - Generic scenario for estimating occupational exposures and environmental releases (Revised draft generic scenario).			
HERO ID:	10480466			
Conditions of Use:	Use - Laboratory Chemicals			
EXTRACTION				
Parameter	Data			
Description of release source:	Container unloading, container cleaning, labware equipment cleaning, during laboratory analyses, waste disposal; Release media: Water, air, landfill			
Release or emission factors:	Release or emission factors			
Release frequency:	260 day/yr			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Assessment uses high quality information/data from frequently-used sources.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	This GS is based on U.S. data
	Metric 3:	Applicability	Medium	Data is for an in-scope occupational scenario; however, data is general and not specific to a chemical.
	Metric 4:	Temporal Representativeness	High	Assessment is based on current industry conditions and data no more than 10 years old.
	Metric 5:	Sample Size	Medium	Sample distribution characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	All data sources, methods, results, and assumptions are clearly documented.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	Variability and uncertainty are not addressed.
Overall Quality Determination		High		

Study Citation:	U.S. EPA, (2022). Chemical repackaging - Generic scenario for estimating occupational exposures and environmental releases (revised draft).			
HERO ID:	11182966			
Conditions of Use:	Repackaging			
EXTRACTION				
Parameter	Data			
Description of release source:	Transfer losses, container cleaning, equipment cleaning, transfer losses during loading.			
Release quantity:	Provides methodology to estimate releases based on various parameters including: opening area of cleaning equipment, physical-chemical properties, air velocity, etc.			
Release or emission factors:	Release or emission factors			
Release frequency:	The number of operating days is given in a range of 174-260 days/yr with an EPA default of 260 days/yr.			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
Comments:	Media: Air, water, incineration, landfillProvides methodology to estimate total emissions for repackaging sites and process steps.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Assessment uses high quality data/techniques/methods from frequently-used sources.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	This GS is based on U.S. data
	Metric 3:	Applicability	Medium	Data is for an in-scope occupational scenario; however, data is general and not specific to a chemical.
	Metric 4:	Temporal Representativeness	Medium	Assessment is generally based on data greater than 10 years old but no more than 20 years old and industry conditions that are expected to be representative of current industry conditions.
	Metric 5:	Sample Size	Medium	Sample distribution characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	All data sources, methods, results, and assumptions are clearly documented.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Uncertainty not addressed. Variability addressed by considering emissions from multiple activities.
Overall Quality Determination			High	

Study Citation:	U.S. EPA, (2021). Use of chemicals in fuels and related products - Generic scenario for estimating occupational exposures and environmental releases (Methodology review draft).			
HERO ID:	11203977			
Conditions of Use:	Fuels and Fuel Additives			
EXTRACTION				
Parameter	Data			
Description of release source:	Unloading transport containers, cleaning transport containers, equipment cleaning, fuel combustion releases			
Release quantity:	Provides models for estimating various fugitive air releases. For combustion, 100% release is assumed and remaining chemical (minus upstream losses) is released			
Release or emission factors:	Release or emission factors			
Release frequency:	365			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
Comments:	Media: air, water, incineration, or landfillEstimation methods: AP-42 emission factors, EPA/OPPT models, Mass balance

Study Citation:	U.S. EPA, (2001). Manufacture and use of printing ink - Generic scenario for estimating occupational exposures and environmental releases (revised draft).
HERO ID:	6311221
Conditions of Use:	Formulation and Use of Printing Ink

EXTRACTION

Parameter	Data
Description of release source:	PROC: Packaging disposal, material transfer, ink processing, equipment cleaning USE: disposal/cleaning of ink container, cleaning printing equipment, ink drying, and disposal of paper.
Release or emission factors:	Release or emission factors
Release frequency:	PROC: 250 days/yrUSE: 250 days/yr
Waste treatment methods and pollution control:	Waste treatment methods and pollution control

EVALUATION

Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	Report uses sound methods from a frequently used source, EPA, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States.
	Metric 3: Applicability	Medium	The assessment is for an occupational scenario within the scope of the risk evaluation but is not specific to chemical.
	Metric 4: Temporal Representativeness	Low	The completed exposure or risk assessment is more than 20 years old (2001). The assessment captures operations, equipment, and worker activities that are expected to be outdated.
	Metric 5: Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics. It is unclear if analysis is representative.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	High	Uncertainty not addressed. Variability is addressed in different ink classes and types of additives considered.

Overall Quality Determination**High**

Study Citation:	U.S. EPA, (2003). Transportation equipment cleaning - Generic scenario for estimating occupational exposures and environmental releases (draft).
HERO ID:	6385708
Conditions of Use:	All

EXTRACTION

Parameter	Data
Description of release source:	Any water soluble heels that are compatible with the facility's treatment system and the conditions of the facility's wastewater discharge permit are usually combined with other wastewaters for treatment and discharge at the facility. Incompatible heels are segregated into drums or tanks for disposal by alternative means, which may include sale to a reclamation facility, landfill, or incineration. The TEC facility may reuse heels comprised of soaps, detergents, solvents, acids, or alkalis as tank cleaning solutions, as neutralizers for future heels, and for wastewater treatment.
Release or emission factors:	nan
Waste treatment methods and pollution control:	Waste treatment methods and pollution control

Study Citation:	U.S. EPA, (1994). Water treatment coagulants application - generic scenario for estimating occupational exposures and environmental releases: Draft.			
HERO ID:	6385760			
Conditions of Use:	Use of Water Treatment Products			
EXTRACTION				
Parameter	Data			
Description of release source:	disposed during use, and loss during solids transfer			
Release or emission factors:	Release or emission factors			
Comments:	Report is specific coagulents used in water treatment. The function of formaldehyde in the COU- Water Treatment Products, is unknown. Therefore, general information on coagulents is extracted and evaluated.			
EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	Report uses sound methods that are from frequently used sources, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The data are from the United States
	Metric 3:	Applicability	Medium	The assessment is for an occupational scenario (use of water treatment products) within the scope of the risk evaluation but is not data specific to formaldehyde.
	Metric 4:	Temporal Representativeness	Low	More than 20 years old.
	Metric 5:	Sample Size	Medium	characterized by uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Assessment or report clearly documents results, methods, and assumptions. Data sources are generally described but not fully transparent.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Uncertainty is not addressed. Variability is considered with different physical forms of the coagulents considered and different sizes of operation.
Overall Quality Determination			Medium	

Study Citation:	U.S. EPA, (2004). Additives in plastics processing (converting) - Generic scenario for estimating occupational exposures and environmental releases - Draft.			
HERO ID:	6549571			
Conditions of Use:	Additives in Plastics Processing (Converting into Finished Products)			
EXTRACTION				
Parameter	Data			
Description of release source:	1. Container residue from plastic resin transport container released to water, incineration, or landfill.2. Dust generation from forming processes released to water or landfill.3. Fugitive air emissions from forming and molding processes released to water or air.4. Equipment cleaning and cooling water from forming and molding processes released to water, incineration, or landfill.5. Solid waste from trimming operations released to water or landfill.			
Release quantity:	Container Residue from Compounding Transport Container: Daily Release from Container Residue (kg/site-day) = Daily Use Rate (kg/site-day) x Loss FractionDust Generation from Converting Activities Released to Water or Landfill: Daily release of dust = daily use rate x loss fractionFugitive Air from Converting Activities Released to Water or Air: Daily release to water (or air) from volatilization = daily use rate x loss fractionResidual from Converting Equipment Cleaning: Daily release from equipment cleaning = daily use rate x loss fractionTrimming Waste: Daily release from trimmings = daily use rate x loss fraction			
Release or emission factors:	Release or emission factors			
Release frequency:	CEB standard assumption, 250 days per year based on 5 day work week and two weeks per year of operation shut down.			
Waste treatment methods and pollution control:	Waste treatment methods and pollution control			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	The assessment uses high quality data and methods that are from a frequently used source and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The data are from the United States and are representative of the industry being evaluated.
	Metric 3:	Applicability	Medium	The assessment is for an occupational scenario within the scope of the risk evaluation. However, data are not chemical specific.
	Metric 4:	Temporal Representativeness	Low	Data are greater than 20 years old.
	Metric 5:	Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Variability is addressed by evaluation of various sources of release, but uncertainty in release estimation is not addressed.

Study Citation:	Baek, K. M., Kim, M. J., Seo, Y. K., Kang, B. W., Kim, J. H., Baek, S. O. (2020). Spatiotemporal variations and health implications of hazardous air pollutants in Ulsan, a multi-industrial city in Korea. Atmosphere 11(5):547.			
HERO ID:	6950643			
Conditions of Use:	disposal			
EXTRACTION				
Parameter	Data			
Description of release source:		Among multi-industrial activities in Ulsan, the petrochemical, oil refinement, and nonferrous metal industries are likely to be major sources of VOCs due to the nature of their operational processes. In addition, shipbuilding and car manufacturing industries are potential sources of VOCs. The atmospheric behavior of formaldehyde is presumed to be different from other VOCs, as not only are they produced from primary sources, such as industrial emissions or vehicle exhaust, but they are also formed in the atmosphere by photochemical oxidation under strong solar radiation and high temperatures. Seasonal concentrations of formaldehyde also substantially increased during the summer, possibly due to secondary formation by photochemical reactions.		
EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	report uses high quality data
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	data are from an OECD country other than the U.S.,
	Metric 3:	Applicability	Low	The report is for a non-occupational scenario that is similar to an occupational scenario within the scope of the risk evaluation
	Metric 4:	Temporal Representativeness	High	The report is no more than 10 years old.
	Metric 5:	Sample Size	N/A	N/A - This metric is not applicable to the data being extracted

Overall Quality Determination		Medium		

Study Citation:	Hawthorne, A.R., Gammage, R.B. (1982). Formaldehyde release from simulated wall panels insulated with urea-formaldehyde foam insulation. Journal of the Air Pollution Control Association 32(11):1126-1131.			
HERO ID:	5957355			
Conditions of Use:	Use of wall panels with urea-formaldehyde foam insulation			
EXTRACTION				
Parameter	Data			
Description of release source:	Formaldehyde emissions may arise both from excess formaldehyde in the original urea-formaldehyde resin, some of which may still be present just after foaming, and from a continuing generation and release due to hydrolysis of the UFFI. The acid catalyst used to complete the polymerization of the UFFI provides an acidic environment, which tends to enhance hydrolytic decomposition and produce continuous formaldehyde release.			
Comments:	Source provides data on formaldehyde in chamber and wall cavities with and without air flow. These concentrations can be translated into emission rates using the chamber / cavity volumes and equation provided in the study. Data evaluated as monitoring data.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Sampling or analytical methodology is an approved OSHA or NIOSH method or is well described and found to be equivalent to approved OSHA or NIOSH methods.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The data are from the United States and are representative of the industry being evaluated.
	Metric 3:	Applicability	Low	The data are for a non-occupational scenario that is similar to an occupational scenario within the scope of the risk evaluation, such as a consumer DIY scenario that is similar to a worker scenario.
	Metric 4:	Temporal Representativeness	Low	Metadata on the operations, equipment, and worker activities associated with the data show that the data agree representative of outdated operations, equipment, and activities rather than current operations, equipment, and worker activities. The data were collected before the most recent PEL establishment or update or are more than 20 years old if no PEL is established.
	Metric 5:	Sample Size	N/A	concentrations can be translated into emission rates
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Low	Description of sources of potential environmental releases
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	limited discussion-Description of sources of potential environmental releases

EVALUATION

Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	Medium	The assessment or report uses high quality data and/or techniques or sound methods that are not from a frequently used source and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	Medium	Danish study, an OECD country.
	Metric 3: Applicability	High	The data are for an occupational scenario (commercial use of building/construction materials – wood and engineered wood) within the scope of the risk evaluation.
	Metric 4: Temporal Representativeness	Low	The report is more than 20 years old
	Metric 5: Sample Size	High	Statistical distribution of samples is fully characterized. Sample size is sufficiently representative
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Assessment or report clearly documents results, methods, and assumptions. Data on type of resin used for particleboard is unclear.
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Low	The report does not address variability or uncertainty.

Study Citation:	Rosenfeld, P. E., Feng, H., L.G. (2011). The petroleum industry. :57-71.			
HERO ID:	6108171			
Conditions of Use:	commercial use			
EXTRACTION				
Parameter	Data			
Description of release source:	Release within petroleum industry arises from leakage, venting, and the evaporation of raw materials and finished products. The operations within a typical refinery emit a wide variety of criteria pollutants and toxic chemicals from fuel combustion devices. Oil and gas field operations as well as gas processing plants are also significant sources of emissions. As such, air emissions consist of point, fugitive, and area sources. Fugitive emissions are the emissions from equipment leaks, such as from valves, storage tanks, and various support equipment. According to the EPA, over 50% of all VOC and toxic air emissions from refineries are fugitive emissions.

The Relationship between Gasoline Composition and Vehicle Hydrocarbon Emissions: A Review of Current Studies and Future Research Needs. Environmental Health Perspectives 102(SUPPL. 4):3.			
HERO ID:	1518425			
Conditions of Use:	Use in Fuels (Vechicle Exhaust)			
EXTRACTION				
Parameter	Data			
Description of release source:	Hydrocarbon emissions increase rapidly when the fuel and air mixture becomes fuel rich. "Single-cyclinder engine studies demonstrated that the total engine-out HC emissions increased as the average molecular weight of the fuel increased. Reduction in T90 also resulted in the reduction of 1,3-butadiene, formaldehyde and acetaldehyde (Table4). The lower formaldehyde and acetaldehyde emissions may be the result of the reduced concentration of the heavier isoparaffins and alkylaro-matics...Replacement of olefins with paraffins and/or aromatics [as well as addition of MTBE] should result in an increase in total HC emissions..."MTBE may be a primary fuel precursor for formaledhyde.			
Comments:	Partial combustion of the isoparaffins and alkyl aromatics would result in an increased formation of methyl and ethyl radicals. These radicals can undergo further reactions(especially under lean con-ditions) to form formaldehyde and acetaldehyde. Primary fuel precursor is MTBE			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1: Methodology	Medium	The assessment or report uses sound methods that are not from a frequently used source and associated information does notindicate flaws or quality issues.

Conditions of Use:	Domestic Manufacture

EXTRACTION	
Parameter	Data
Description of release source:	Formaldehyde productionProcess Emissions– Silver Catalyst Process – The primary source of formaldehyde process emissions is the purging of gases from the secondary absorber. The product fractionator is another possible source of formaldehyde process emissions. However, most producers report that gases from the fractionator are fed to the absorber before venting. Formaldehyde emissions also occur during plant startup. Formaldehyde plants are normally operated at design conditions to achieve highest yields and are shut down when product inventories are filled. The silver catalyst process operates above the upper explosive limit of methanol. Thus, plant startup procedures must be handled carefully. Unstable conditions are encountered, and explosions can occur in the methanol vaporizer and the reactor. Various startup procedures are used in the industry. During startup, the output from the reactor may be vented until stable operation is achieved and an acceptable yield ratio is obtained. The flow is then switched into the absorber. Most formaldehyde producers report that startup vents go through the absorber before venting to the atmosphere. Total startup time is usually 1 to 2 hours. The reactor feed rate varies as the startup proceeds. Initially, the reactor produces mainly carbon dioxide and water vapor. As the temperature rises, the formaldehyde yield increases, thereby increasing the amount of formaldehyde in the vented gas. Startup emissions, when venting through the absorber, are reported to be 0.1 kg/Mg. Metal Oxide Catalyst Process– The metal oxide catalyst process operates below the explosive limit of methanol with an excess of air resulting in stable conditions during startup. Thus, venting of the reactor during startup is not required as it was for the silver catalyst process, and there are no intermittent startup emissions. Formaldehyde process emissions result from venting gases from the product absorber. The emission composition and flow rates are affected by the percent of absorber gas recycled. By recycling a portion of the oxygen-lean vent gas, the oxygen concentration in the reactor feed mixture can be reduced, making it possible for the concentration of methanol to be increased without forming an explosive mixture. This reduces the volume of reaction gases and thus reduces the emission rate of formaldehyde from the absorber.Storage Emissions– Formaldehyde emissions result from storing formaldehyde product. Formaldehyde storage emissions were estimated based on an average of four tanks per plant, a tank size of 190 cubic meters, 45 turnovers per year, and a bulk liquid temperature of 54°C. The tanks were assumed to be fixed-roof, half full, and subject to a diurnal temperature variation of 11.1°C.Handling Emissions- Emission factors from the handling of formaldehyde product were calculated assuming submerged fill-pipe loading into trucks and tank cars.Fugitive Emissions– Fugitive emissions of formaldehyde and other volatile organics result from leaks in process valves, pumps, compressors, and pressure relief valves. The rate of fugitive emissions of formaldehyde from these sources was calculated from the number of pumps, valves, compressors, and relief valves in formaldehyde service, the estimated formaldehyde concentration in streams in contact with these sources, and emission factors for fugitive sources.

Conditions of Use:	Reactant Resin Manufacture			
EXTRACTION				
Parameter	Data			
Description of release source:	Urea-formaldehyde and Melamine-formaldehyde resin productionFormaldehyde emissions from the polymerization process occur while water is being removed from the reactor under vacuum and during the cleaning of the reactor kettles between batches. Fugitive gaseous emissions may occur from relief valves, pumps, valves, and flanges. Potential formaldehyde emission sources in spray drying operations are belt driers, continuous drum dryers, and continuous screen dryers that are vented to the atmosphere. Urea-formaldehyde and M-F production plants may vary in configuration and level of control. The level of control on formaldehyde storage emissions should be equivalent to that for formaldehyde production. The reader is encouraged to contact plant personnel to confirm the existence of emitting operations and control technology at a particular facility prior to estimating its emissions.

EXTRACTION				
Parameter	Data			
Description of release source:	PHENOL-FORMALDEHYDE RESIN PRODUCTION Formaldehyde emissions from the production of resols and novolaks may result from the storage of formaldehyde before it is charged to the reactor and from the distillation and dehydration of the reaction mixture. Carbon adsorption or liquid extraction is used to control emissions from these operations. Fugitive gaseous emissions may occur at the condenser, vacuum line, sample ports, and vents of both processes. Intermittent formaldehyde emissions occur at safety blow-off valves. Formaldehyde emissions also may result from washing reactor kettles. Water washing of some resols during product preparation may produce formaldehyde emissions. Phenol-formaldehyde production plants may vary in configuration.

Conditions of Use:	Reactant process aid			
EXTRACTION				
Parameter	Data			
Description of release source:	SOLID UREA AND UREAFORM PROCESSINGFormaldehyde is emitted during the urea solids production process, specifically related to fluidized bed prilling and drum granulation operations. Uncontrolled emission rates from prill towers may be affected by factors such as product grade being produced (agricultural or feed grade), air flow rate through the tower, type of tower bed, and ambient temperature and humidity. Uncontrolled emissions per unit of production are usually lower for feed-grade prills than for agricultural-grade prills due to lower airflows. Emission rates from drum granulators may be affected by parameters such as rotation rate of the drum, product size, recycle rate of seed material, bed temperature, solution spray pressure, and airflow rates through the drum.

EXTRACTION				
Parameter	Data			
Release quantity:	Furniture ManufacturingIn the absence of furniture plant formaldehyde emissions data, the available range of particleboard manufacturing formaldehyde emissions data may be used to predict a worst-case formaldehyde emissions estimate for furniture manufacturing. This estimate is possible because both industries use similar U-F adhesive resins and both utilize board pressing operations at elevated temperatures and pressures.However, in furniture plants it is possible that a smaller percent of the excess formaldehyde in the adhesive resin is emitted than in particleboard plants. Formaldehyde emissions from furniture plants are probably lower because: (1) presses in furniture plants operate at much lower temperatures, (2) furniture presses have somewhat shorter cycle times than those in particleboard plants, and (3) the physical configuration of furniture pieces is different than that of particleboards. (In a furniture piece, a veneer barrier protects the major glue surface from direct exposure to air, while no such continuous barrier inhibits formaldehyde evaporation during the particleboard pressing cycle.)

HERO ID:	1256822			
Conditions of Use:	combustion - oil refinery			
EXTRACTION				
Parameter	Data			
Description of release source:	Combustion Oil RefiningFormaldehyde is emitted with combustion products from refinery process heaters, boilers, and internal combustion compressor engines. These combustion sources are located throughout the refinery. Process vent streams from catalytic cracking and fluid coking operations also contain formaldehyde. These streams are discharged from boilers used to burn CO-rich waste gas streams. In catalytic cracking, the CO-rich waste stream results from the partial air oxidation of catalyst coke deposits, while in fluid coking, the CO stream results from the partial oxidation of the coke burned to provide process heat.There is no corresponding process vent stream from the delayed coking operation. Refinery unit operations include valves, pumps, flanges, and other hardware, all of which emit fugitive hydrocarbons. These hydrocarbons are not, however, expected to contain large amounts of formaldehyde.Emissions from external combustion sources (boilers and process heaters) and internal combustion engines are discussed in the section of this report entitled COMBUSTION SOURCES.

HERO ID:	1256822
Conditions of Use:	Reactant wood products

EXTRACTION	
Parameter	Data
Description of release source:	Pressed-wood Manufacturing Emissions from pressed-wood products result as compounds in the resin used to bind the chips evaporate when heated. These emissions usually exit through exhaust fans mounted on the roof above the presses. The type of resin used and, thus, the compounds present in its formulation vary depending upon the type of panel being manufactured. The U-F resins are primarily used in the production of particleboard and medium-density fiberboard. These panels typically contain 8 to 9 percent (w/w) resin. The U-F resin is used in applications where the final product will not be subject to weathering. The P-F resins are used in the production of particleboard, waferboard (WB), and oriented strand board (OSB). Structural particleboard made with P-F resins contains approximately 7 percent (w/w) resin, and WB and OSB contain approximately 2 percent (w/w) resin. The P-F resins are more resistant to moisture than U-F resins. The National Council of the Paper Industry for Air and Stream Improvement (NCASI) published two technical bulletins in 1986 that investigated the release of formaldehyde from press vents in the wood panelboard industry. One NCASI study concluded that three major factors affect the release of formaldehyde from press vents: (1) the excess formaldehyde content of the resin, (2) the amount of resin used, and (3) the press temperature. These factors are discussed below. Excess formaldehyde is the amount of formaldehyde in the resin in excess of the amount required for stoichiometric reaction with the urea or phenol in the resin. The emission rates have been shown to increase in proportion to the increase in the free formaldehyde content of the resin. The excess or free formaldehyde contents of resins are often held proprietary by resin manufacturers. NCASI showed that where such information was available, the data indicated that 5 to 15 percent of the excess formaldehyde in the panelboard was emitted during the pressing and board cooling operations. One method to determine the potential of resins to emit formaldehyde during particleboard manufacture would be to use the excess formaldehyde content of the resin (calculated on the basis of the amount of formaldehyde in excess of the amount needed to react stoichiometrically with the other reactive constituents in the resins). However, resin manufacturers will not divulge sufficient information about their resins to allow these calculations to be made. The NCASI study showed that the emission rate of formaldehyde increased in proportion to the amount of resin used in the panelboard and the press temperature. The NCASI study also showed that the formaldehyde emissions from particleboard press vents are related to the amount of excess formaldehyde in the unpressed boards loaded into the press. It would appear that formaldehyde emission rates could be reduced by using less excess formaldehyde in the resin. The industry has already decreased the amount of excess formaldehyde in resins in order to reduce the emissions of formaldehyde from the finished product into the living or work space. This reduction of excess formaldehyde in the resin also resulted in longer press times and, hence, reduced production rates. In an effort to eliminate the potential for formaldehyde emissions, methylene diphenyl diisocyanate (MDI) resins have been used by some manufacturers. The MDI resins produce a higher-strength panel than do the U-F or P-F resins. Therefore, manufacturers are able to use less MDI resin to meet the industry's product standards. However, MDI resins are much more expensive than U-F or P-F resins, and panels produced with MDI resins tend to stick to the presses. Two approaches have been used to prevent the panels from sticking. One is to spray the presses lightly with an antisticking agent between press cycles. Another approach is to use U-F or P-F resins to bind the material on the two outer surfaces of the panel. The core of the panel is bound with the MDI resin. This reduces the amount of formaldehyde available to volatilize, and the panel retains the structural strength provided by the MDI resin. In addition to press vents, wood furnish dryers are also sources of formaldehyde emissions. In a study by NCASI designed to determine the emission rates of formaldehyde and other compounds emitted from wood furnish dryers, a range of typical emission factors were developed for use in preparing emission estimates for air discharge permits. The study indicates that the concentration of formaldehyde in the dryer exhaust is a function of the dryer inlet temperature. The formaldehyde emission rate at dryer inlet temperatures below 900°F was less than 0.085 lb/ton of product. At inlet temperatures above 1000°F, the formaldehyde emission rates ranged from 0.01 to 1.1 lb/ton of product.

HERO ID:		8016661			
Conditions of Use:		Use of ink, toner, and colorant products			
EXTRACTION					
Parameter		Data			
Process description:		The printing operation at WCP is an automated lithography (off-set) process that prints, dries, cuts, folds, and assembles magazines into a crude form called signatures. The 12 high-speed printing presses in operation are manned by printing press operators. Four types of colored inks (black, blue, red, and yellow) are printed on wide-web rolls of bleached paper. The chemical composition of inks varies, but most include a complex mixture of pigments, petroleum distillates, and resins (including epoxy and phenolic resins). Some magazine covers require a varnished finish that is applied by catalytic coating units on presses #219 and #228. This varnish coating contains 2-butoxyethanol. After printing and coating, the ink is dried by gas-fired dryer ovens operating at 350°F. Signatures are then cut, folded, assembled, and prepared for binding. Local exhaust ventilation (LEV) is present at catalytic units and dryer ovens of each press. Numerous roof exhaust fans are present throughout the plant. During the printing operation, workers routinely use blanket wash solutions and wetting agents (also called fountain solutions) as solvent cleaners to remove ink from printing press equipment. These solvents are manually applied by workers using shop rags while wearing nitrile rubber gloves for hand protection. Press equipment is partially cleaned or wiped down about 2-3 times each shift. A more thorough cleaning on each press is done a few times each week, with cleaning sessions lasting about an hour. Some cleaning tasks require three workers several hours to accomplish. Some printing presses have an auto-blanket wash system that is capable of cleaning during operation. Blanket wash solutions are combustible liquids (flashpoint greater than 100°F) made of petroleum naphtha. Wetting agents (flashpoint less than 100°F) are made of alcohol or an alcohol substitute. Over the course of a workday, solvent-saturated shop rags are accumulated and stored in metal orplastic containers. An anti-static silicon solution is also handled by workers during printing. The anti-static solution is manually applied to press rollers several times each shift to achieve a certain print quality.

HERO ID:	6302987		
Conditions of Use:	Domestic Manufacturing		
EXTRACTION			
Parameter	Data		
Process description:	At an industrial scale, formaldehyde is manufactured by catalytic oxidation of methanol via either a silver or metal-oxide catalyst process. Production capacity is split almost equally between production processes which use the silver catalyst process and those which use oxide manufacturing processes. In the metaloxide process, methanol is oxidised with excess air in the presence of a modified ironmolybdenum-vanadium oxide catalyst at 250-400 °C and atmospheric pressure (methanol conversion of 98-99%) (IARC11, 2006) (pg.9)		
Throughput:	The world production capacity of Formalin is 40 million tonnes per year of which Europe represents around 25% with a production capacity of 9.5 million tonnes per year (Merchant Research and consulting, 2012, quoted in RPA/TNO, 2013).Formaldehyde is registered under REACH in quantities >1 million tonnes per year. The total formaldehyde production in Europe (EU28 + Norway + Switzerland) is around 3.2 million tonnes as 100% pure formaldehyde, which is equivalent to 8.6 million tonnes as 37% water solution. (pg. 9)		
Chemical concentration:	Formaldehyde is commonly not produced in pure form as it is not stable. Formal or Formalin is usually produced instead with 30-50% of formaldehyde. (pg. 9)

EXTRACTION

Parameter	Data
Process description:	Urea is manufactured from liquid ammonia and gaseous carbon dioxide (CO₂) at elevated pressures and temperatures; both reactants are typically obtained from an ammonia-synthesis plant. Urea plants are usually located adjacent to ammonia production facilities which conveniently furnish not only the ammonia but also the CO₂, because CO₂ is a by-product of ammonia production and purification. Plants #1 and #4 at the Kenai facility are ammonia-synthesis plants that supply the reactants to the urea producing plants. The remaining plant (Plant #3) generates power for the entire Kenai facility. The ammonia and CO₂ are fed to a high pressure reactor at temperatures of about 200 degrees Celsius (°C) where ammonium carbamate is formed as an intermediate compound, which is simultaneously dehydrated to form urea. Although, the reaction to form the ammonium carbamate is complete at elevated pressures, the reaction to form the urea is incomplete under all practical conditions. Because an excess of ammonia (typically a 4:1 ratio) is fed to the reactor, and because the reactions are reversible, ammonia and CO₂ exit the reactor along with the ammonium carbamate and urea. The ammonia, CO₂, and ammonium carbamate are then recycled back into the reaction process. Purification of the ammonia, CO₂, and ammonium carbamate in the liquid stream from the reactor achieves a urea solution of about 72%. After the reaction process and the removal of the by-products for recycling, the urea in solution is crystallized, centrifuged, dried, melted, and finished by either prilling or granulation. Of the two plants that produce the urea, one produces urea in the prill form while the other produces granular urea. Worldwide, prilling is the most widely used method of solidifying urea, but the use of granulation is increasing rapidly. Urea prilling is the more economical method for finishing, but the prills have low strength and are generally too small for use in blending with granular materials such as diammonium phosphate. Also, the prilling operation is a serious polluter, the abatement of which is costly because of the large volume of dust-laden air that must be treated. For these reasons, there is a strong trend toward granulation of urea. Although prilling is still the most widely used method worldwide, granulation is now the leading method of finishing urea in the United States. In prilling, molten urea that is almost anhydrous is forced through spray heads or spinner buckets at the top of a tower to produce droplets that fall through a countercurrent stream of air in which they solidify to form prills. The prills are collected at the base of the prill tower by a rotating rake and dumped onto a conveyor that feeds the prill bucket elevator. The prills are then elevated to the prill screens where undersized and oversized prills are removed. The undersized and oversized prills are collected and returned to the crystal melt tanks for reprocessing. The final product is then transported to a storage building by a series of conveyors. The granular urea is produced in Plant #5. In this process, granules are formed by the successive spraying and drying (layering) of concentrated urea solution on recycled granules in a rotating drum. Special design of the drum and sprays, together with the control of air flow, results in hard granules of particle sizes favorable for blending and other use. Spraying occurs primarily in the first third of the granulator; the remaining portion is used mainly as a rotary cooler. The cooled granules discharge from the drum and are screened into oversize, undersize, and product size. The oversized granules are crushed and returned to the front of the granulator as recycle along with the undersized to form seed. As the recycled urea seed passes through the granulator, the sprayed molten urea impinges on them and the granules are grown. The final product is then transported to a storage building. The finished granules and prills are stored in separate warehouses while awaiting shipment. Most of the urea fertilizer is transported from the Kenai plant by ocean freighter. The urea storage warehouses are equipped with overhead conveyor systems to distribute the finished urea in the warehouse and subfloor conveyor systems to transport the product to the wharf for loading. The conveyors are located in the center and run the length of both warehouses. The floors of the warehouses are equipped with a series of grates that open to the subfloor conveyor system. The urea falls from the overhead conveyor onto the warehouse floor forming large mounds of the finished product. The urea then falls through the opened grates onto the subfloor conveyor that transports it to the wharf where it is loaded into the holds of a freighter. Both the conveyors and the grates are controlled so that the warehouses are filled evenly. Two large loaders are used in the warehouses to aid the loading operations by moving the urea over the floor grates and dislodging urea that has caked together. During both the prilling and granulation processes, UF-85 is added to the molten urea prior to finishing. Formaldehyde, such as in the UF-85, has been widely used in the production of urea since the mid- 1970's as a conditioning agent to harden the product, reduce dust generation during handling, and provide anti-caking properties in storage. Approximately 95% of the domestic urea fertilizer producers condition their urea with a formaldehyde-based additive (ureaforms) and virtually all solid urea producers employ some type of conditioning agent to improve product handling. The Kenai facility produces approximately 1 million tons of urea and 1 million tons of ammonia per year. Plant #2 was built in 1968 and produces from 1250 to 1450 tons of the prill urea per day. The granular urea is produced in Plant #5 which became operational in 1978. Plant #5 typically produces from 1700 to 1800 tons of the granular urea per day.
Throughput:	
Number of sites:	1 facility with 5 plants (#2 and #5 are used to produce urea fertilizer.
Chemical concentration:	The UF-85 is a liquid mixture containing 60% formaldehyde, 15% water, and 25% urea.

Overall Quality Determination			High	

Study Citation:	NIOSH, (1976). Health hazard evaluation determination: corhart refractories.			
HERO ID:	8687978			
Conditions of Use:	Plastic and rubber products			
EXTRACTION				
Parameter	Data			
Process description:	The no-bake mold department is one of three areas in this plant that produce sand molds into which molten silica and alumina are poured to produce the refractory product sold by Corhart to the glass industry. Dry sand at approximately 90°F. is mixed with binders in an auger type mixer and dropped about four feet into the forms which shape the molds. In about five minutes the mold hardens due to the plasticizing of t he phenol-formaldehyde resin. The molds are then separated from the forms, in some cases fitted with a top or core, and transported from the area. Until they are removed from the area, however, these fresh molds continue to off-gas into the atmosphere. Approximately sixteen men are involved in this operation.

Conditions of Use:	Adhesive and sealant chemicals in wood product manufacturing

EXTRACTION	
Parameter	Data
Life cycle description:	Formaldehyde is used in formaldehyde resin glue that is used as an adhesive for the production of fiber and particle boards. The formaldehyde is then emitted during hot pressing operations.
Process description:	The simplest veneered panel consists of three plies, a face and a back veneer glued to each side of a core. Additional plies may be added to make a panel which is stronger and more stable dimensionally. An established way to achieve a high rate of production is to reduce the glue-curing time by heating the glue while pressure is being applied to the panels. One way to do this is to heat the metal plates which apply the pressure, generally referred to as "hot-press II process. Another way is to generate heat in the glue-line with radio-frequency (R/F) radiation in much the same way that food is cooked in a microwave oven. In this "R/F-press" process, the hydraulic press only applies pressure. "cold-press" processes, those for which pressure is applied while the boards—and glue—are maintained between 60 and 100F, require much longer periods of time for the glue to cure. For most applications, the glue which currently provides the best performance for the least cost is a urea/formaldehyde (U/F) resin adhesive. The core may be a sheet of veneer, particleboard ("chip-core") or fiberboard, or a piece of edge-glued solid-wood "lumber-core". Almost all particleboard and fiberboard are made with formaldehyde resin binders, and a formaldehyde resin glue may be used to assemble lumber-core. To improve the appearance of a panel, the core may be "banded" with solid wood edges prior to veneering. Here again, the adhesive may contain formaldehyde. A variety of hardwoods and softwoods, including oak, walnut, poplar, and pine, are used for veneer stock. Some plastic laminates are being used for certain products; usually these panels are cold-pressed. The veneers are received in flitch form, thin strips bundled together as they were cut from the log. The veneer flitches are pressed, trimmed, and joined into sheets, which are then cut to the proper size for the panel being produced. Core stock is received already cut into pieces of the appropriate nominal size and banded, if desired. This plant does not have facilities for manufacturing lumber-core. About 70% of the flat panels produced use chip-core, and about half of this quantity is banded. The remainder is lumber-core; very little fiberboard is used. Five-ply panels, from all types of cores, make up most of the total production. Large curved panels are not made here, the only other veneering involves small parts and frames. Hot-press veneering is accomplished mostly on a Wemhoner feed-through press. Heat and pressure are applied for from less than 2 to over 3 minutes, depending on the panels being processed. Two workers are assigned to the Wemhoner: a loader and an unloader. The process is highly automated. A steam-heated, two-level shuttle press is still used, but mostly for flattening sheets of veneer. It is used for pressing panels only when the feed-through press is not being used. The panels are prepared for pressing by the glue-spreader crew. Two or three people are assigned to the glue spreader. The appropriate layers are passed through the glue spreader, and the stack of panels is built-up like a pile of sandwiches. The stack is moved to the loading end of a press on roller conveyors.

EXTRACTION				
Parameter	Data			
Process description:	In the centrifugal forming processes (aerocor and standardinsulation) glass batch is fed into the furnace where boro-silicateglass is formed at temperatures of approximately 2500°F. The molten glass next flows into a smaller refractory container known as a forehearth where the temperature is held at approximately 2200°F. The molten glass flows from the forehearth by gravity into spinners where centrifugal force is used to force the glass through small holes in the periphery of the spinner thus fanning primary fibers. Upon leaving the spinners, each glass fiber is met by a high velocity burner flame which further attenuates the fibers. A phenol-formaldehyde binder (containing ammonia) also is sprayed onto the fibers at this time. The fibers, coated with binder, are collected on a conveyer thus forming a continuous blanket. The blanket next passes through a curing oven {400-500°F) causing the phenol-formaldehyde binder to polymerize. If a high density product is desired, the blankets also may be compressed during curing. After curing, the blankets are cut and trimmed and eithercompression packaged or taken to another area for further fabrication (aerocor fabrication).

HERO ID:	3840003			
Conditions of Use:	Adhesives and Sealants; Paint and coatings			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	211 million lbs of rad-cur materials produced in 2005			
Process description:	Describes formulation process, application process, typical formulations.			
Number of sites:	715 (appears to be total number of sites from Table 3-2)			
Chemical concentration:	depends on function, no specific to formaldehyde			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1: Methodology	High	The assessment or report uses high quality data and/or techniques or sound methods that are from a frequently used source (e.g., European Union or OECD reports, NIOSH HHEs, journal articles, Kirk-Othmer) and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States and are representative of the industry being evaluated.	
	Metric 3: Applicability	High	The assessment is for an occupational scenario within the scope of the risk evaluation.	
	Metric 4: Temporal Representativeness	Medium	The assessment captures operations, equipment, and worker activities that are expected to be reasonably representative of current conditions. The completed exposure or risk assessment is generally, more than 10 years but no more than 20 years old.	
	Metric 5: Sample Size	High	Statistical distribution of samples is fully characterized. Sample size is sufficiently representative.	
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions	
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Medium	The assessment provides only limited discussion of the variability and uncertainty in the results.	
Overall Quality Determination		High		

Study Citation:	OECD, (2010). Emission Scenario Document on Photoresist Use in Semiconductor Manufacturing.			
HERO ID:	3840005			
Conditions of Use:	Commercial Use (Electrical and electronic products (including semiconductors))

EXTRACTION			
Parameter	Data		
Production, import, or use volume:	Formaldehyde is a major industrial chemical, ranked 24th in production volume in the United States. In 1985, 5.7 billion pounds of 37 percent formaldehyde (by weight) was produced. Formaldehyde has four basic uses: As an intermediate in the production of resins; as an intermediate in the production of industrial chemicals; as a bactericide or fungicide; and as a component in the formulation of end-use consumer items. The manufacture of three types of resins: urea-formaldehyde, phenolformaldehyde, and melamine formaldehyde, accounts for about 59 percent of total consumption. An additional seven percent is consumed in the production of thermoplastic acetal resins. About one-third is used in the synthesis of high volume chemical derivatives, including pentaerythritol, hexamethylenetetramine, and butanediol. Two percent is used in textile treating and small amounts of formaldehyde are present as preservatives or bactericides in consumer and industrial products, such as cosmetics, shampoos and glues. Some products prepared from formaldehyde contain unreacted formaldehyde residues which may be released from the product over its useful life. One example is urea-formaldehyde resin. Urea-formaldehyde resin is a generic name that actually represents an entire class of related formulations. Over 60 percent of ureaformaldehyde resin production in 1977 was consumed by particleboard and plywood manufacturing, where the resin is used as a glue. Urea-formaldehyde resins are also used in decorative laminates, textiles, paper, and foundry sand molds. Formaldehyde resins are used to treat textiles to impart wrinkle-resistance to clothing. About 60-85 percent of all apparel fabric is finished with formaldehyde-containing resins. As apparel manufacture is the sixth largest industry sector in the United States, this use is the major source of widespread exposure to formaldehyde because of the large number of workers potentially exposed. Formaldehyde destroys bacteria, fungi, molds, and yeast. Its commercial importance as a fungicide is probably its greatest use as a disinfectant. Because of its bactericidal properties, formaldehyde is used in numerous cosmetic preparations. Formaldehyde’s uses can lead to widespread exposure in downstream industries. For example, when formaldehyde is present in disinfectants, preservatives, and embalming fluid, worker exposure can occur. Although formaldehyde changes into other chemicals when urea-formaldehyde resins and concentrates are produced, decay may occur, causing workers in numerous industries including wood products and apparel manufacture to be exposed to airborne formaldehyde when it off gasses from products’ manufactured with these resins.		
Life cycle description:	All lifecycle processes and uses		
Number of sites:	Table 1 (page 22300 or pdf pg 154/268) provides details concerning the number of establishments for different levels of exposure for 35 different industrial sectors.		
Comments:	This is the notice that sets the most recent PEL

Study Citation:	Rodriguez, Manuel, M., Aristeguieta, C. (2009). Evaluation of employees’ chemical exposures while blending and repackaging glass beads for road markings.			
HERO ID:	8684530			
Conditions of Use:	Paints and coatings			
EXTRACTION				
Parameter	Data			
Process description:	Employees blend and repackage the beads in smaller paper sacks or boxes for distribution to state transportation departments and other customers. The glass beads are applied over wet paint sprayed on road surfaces to make street markings reflective to automobile headlights. The beads vary in size from 0.2–1.2 mm and have a silane coating. The repackaging process begins with lifting a Super Sack with a forklift over a metal bin, then cutting the bottom of the container with a knife to empty the beads into the bin (Figure 1). The metal bin is lifted by a forklift, and the glass beads are poured into hoppers. From the hoppers the beads are gravity fed into smaller cardboard boxes or paper sacks that are shipped to customers (Figure 2).

EXTRACTION	
Parameter	Data
Process description:	The cans are formed from coiled aluminum sheet by the so-called draw and wall- iron method in which a "cup" is formed in a special press and forced through a redraw die and "3 wall ironing rings". In this step the can is drawn tp full length and thickness. The hemispherical shape of the bottom is also formed . After the tops of the cans are trimmed to obtain burr- free edges they are washed and treated (acid and alkali wash) in preparation for the application of inner and outer coatings. There are four washing/treating machines located on the upper deck. cans from the washing operation are conveyed to one of four machines in which a water- based coating (called base coat) is applied from a system of rollers. As the cans leave the basecoat application rollers they are moved by a continuous "pin" conveyor, with each can being held on a 5-in. spindle or "pin" from the inside, to oneof four "FECO" pin-ovens in which the basecoat (either white or clear during the visit) is cured.The FECO ovens are divided into two sections . In the first section the basecoat is cured at 400°F in an indirect natural .gas- fired curing section. Air (for both combustion and ventilation) is supplied to the curing section and exhausted to the outside through a 30-foot stack. The cans exit the curing section and enter the cooling section, where filtered ambient-temperature air is blown and exhausted to a stack. The FECO ovens were designed for negative pressure operation.The basecoated cans exit the FECO oven through a chute and are conveyed to the decoration or "deco" machines where brand name and other information is printed. Inks of various colors are applied by a system of rollers in four deco machines, which have, the capability of applying up to four colors simultaneously. The cans are then conveyed by pin conveyor to FECO ovens, where the ink is cured in the same fashion as the basecoat. Following the ink cure, five machines on the first floor are used toapply an epoxy inner liner; the solution is sprayed from stationarynozzles. The cans are positioned by a rotating star-shaped wheel(turret) . The spray from the nozzles is intermittent and issynchronized so that it occurs only when a can is in place. The cansare then conveyed -to one of four curing ovens by one of four conveyors, each having horizontal and vertical runs. As in the case of FECO ovens, the inner spray "DESPATCH" curing ovens have two sections, one for curing and the other one for cooling. The cans exiting the DESPATCH oven are conveyed to a machine which forms a neck and a flange into the top portion where the end will be applied after the can is filled. After being tested for leaks, the cans are palletized and the pallets are strapped with 112 in. wide plastic film before shipping. The plant operates continuously with two 12-hour shifts per day. At maximum capacity, four lines may be in operation simultaneously; with each line producing 500,000 cans per shift.
Throughput:	The Metal Container Corporation manufactures two-piece aluminum beverage containers at the rate of 4,000,000/day.

Study Citation:	U.S. EPA, (2002). Flexographic ink options: A cleaner technologies substitutes assessment. Volume 1.			
HERO ID:	10293388			
Conditions of Use:	Ink, toner, and colorant products.			
EXTRACTION				
Parameter	Data			
Process description:	Flexography is a process used primarily for printing on paper, corrugated paperboard, and flexible plastic materials. Flexography uses a soft, flexible printing plate that is mounted on a rotary cylinder. Flexographic presses are equipped with anywhere from one to as many as twelve color stations. Examples of items printed with flexography include comics, newspapers, appliance boxes, and many grocery store packages - including cereal boxes, shampoo and soda bottle labels, frozen food and bread bags, and milk cartons.Solvent-based inks are widely used in many flexographic printing processes. They were the first printing inks to be available commercially. Historically they have been very popular because they dry quickly, perform well, and allow printers a wide choice of products. Solvent-based inks are generally considered to be the industry standard for ease of use and quality of printing.Solvents are important in delivering the ink to the substrate. The solvent allows the ink to flow through the printing mechanism, and then evaporates so that the ink forms a solid coating on the substrate. Typically, inks are manufactured and transported in a concentrated form, and the printer must add solvent to the ink to attain the desired viscosity. A solvent must display several important characteristics. It must adequately disperse or dissolve the solid components of the ink, but must not react with the ink or with any part of the press. It must dry quickly and thoroughly, and have low odor. Finally, it is desirable for the solvent to have minimal flammability and toxicity concerns.			
Number of sites:	550 firms manufacture printing inks in the U.S.

Overall Quality Determination		High		

Study Citation:	U.S. EPA, (2022). Chemical repackaging - Generic scenario for estimating occupational exposures and environmental releases (revised draft).		
HERO ID:	11182966		
Conditions of Use:	Repackaging		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	Table B-1 presents data on repackaging rate in kg chemical/site-yr.		
Process description:	"Pre-manufacture notices (PMN) submitted from 2010 to 2020 under EPA’s New Chemicals Program indicated imported and repackaged chemicals can be solids or liquids and may be neat or in solutions/mixtures and contained in various packaging types. After they arrive at the repackaging site, repackaging operations occur where the chemical is transferred from the transport container it was imported in to a new one of a different size in order to meet the customer’s needs (JACO, 2021). Chemicals may also be transferred from original containers to intermediate storage containers before packaging into smaller containers (Cooke, 2013; NIOSH, 2009). Chemicals are expected to be received at repackaging sites in drums or larger bulk containers (supersacks, totes, tank trucks, etc.) (Cooke, 2013; NIOSH, 2009). The chemical of interest may be received in its final formulation and transferred directly from these large containers into smaller containers, charged to a temporary storage tank, or it may be charged to a mixing tank and diluted or mixed with other chemicals before it is repackaged. Once the chemical has been formulated to desired specifications, it can be repackaged. Workers may be potentially exposed during the unloading of chemicals from the original transport containers into temporary storage or new transport containers. Releases of chemicals may also occur during this stage, from open container surfaces (e.g., if the chemical is volatile), transfer operations (e.g., if the chemical is volatile or a powder), and original transport container disposal.Repackaging operations for liquid chemicals typically involve pouring or pumping the product from the original containers or mixing /storage tanks into the new containers. A study conducted by the Health and Safety Laboratory in the U.K. investigated two chemical repackaging sites (Cooke, 2013). At both of these sites the chemical was delivered to the site by road tanker and pumped into dedicated storage tanks. One of the sites, a hydrazine supplier, pumped the hydrazine into a mixing vessel where it was diluted with water and packaged into smaller containers for sale to customers. At the other site, trichloroethylene was pumped from storage tanks into a closed loop system where workers using a hydraulic lance connected to a semi-automated filling system transferred the chemical into new containers (Cooke, 2013). The usual process for repackaging solid chemicals differs from the processes for liquids. A NIOSH Health Hazard Evaluation Report (HHE) from 2009 investigated a repackaging facility that was transferring bulk shipments of silane-coated glass beads ranging between 0.2 – 1.2mm in diameter. At this facility, 2,200 lb supersacks of the product are lifted with a forklift over a metal bin, then cutting the bottom of the container with a knife to empty the beads into the bin. The metal bin is then lifted by a forklift, and the glass beads are poured into hoppers. From the hoppers the beads are gravity fed into smaller cardboard boxes or paper sacks that are shipped to customers (NIOSH, 2009). Workers may be potentially exposed during the transfer of chemicals from temporary storage into new transport containers. Releases of chemicals may also occur during this stage from open container surfaces (e.g., if the chemical is volatile), transfer operations (e.g., if the chemical is volatile or a powder), and cleaning any equipment that was used in during the process."		
Throughput:	The number of operating days is given in a range of 174-260 days/yr with an EPA default of 260 days/yr.		
Number of sites:	Table 1-2 presents the number of repackaging sites based on 2019 U.S. Census data.		
Chemical concentration:	A fraction of completed IRERs from 2010-2020 were reviewed, 21 submissions contained information on chemical repackaging. In these submissions, chemicals were repackaged at concentrations ranging from 1% to 100%, with a 50th percentile of 93%, a 95th percentile of 100%, and a mode of 100%.

Study Citation:	U.S. EPA, (2021). Use of chemicals in fuels and related products - Generic scenario for estimating occupational exposures and environmental releases (Methodology review draft).			
HERO ID:	11203977			
Conditions of Use:	Fuels and Fuel Additives			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	95.3 billion gallons of gasoline were sold in 2018.			
Process description:	Chemicals in fuels and related products are expected to be received at use sites (i.e., fueling stations) via tank trucks, rail cars, tankers, barges, and pipelines. The fuels are then transferred from these transport containers to on-site storage tanks, typically through pipes and hoses. At the use site, fuels are dispensed from storage tanks to vehicles or other equipment. Storage tanks for fuel are typically underground, and fuel is pumped upwards through tubes and nozzles. During combustion, fuel is burned to provide energy to an engine. In a typical internal combustion engine, fuel is mixed with air in a chamber. This mixture is ignited with a spark and energy from the burning fuel is used to power the vehicle or machine. Exhaust gases leave through a tailpipe or vent.			
Throughput:	365 days/yrProvides methodology for estimating throughput based on use rates and operating days/yr.			
Number of sites:	Up to 505,698 sites (Table 1-2)			
Chemical concentration:	Table 1-1 provides concentration ranges (with example chemicals) of typical fuel additives.

Study Citation:	U.S. EPA, (2000). Leather dyeing - Generic scenario for estimating occupational exposures and environmental releases (draft).			
HERO ID:	6311220			
Conditions of Use:	Leather dyeing			
EXTRACTION				
Parameter	Data			
Process description:	Leather is generally dyed in wooden drums or rotating vessels. A dye bath is prepared by adding a dye stuff to the dyeing equipment; surfactants and other auxiliaries may also be added. The bath temperature may range from 0 to 60C. The leather is brought into the drum or rotating vessel, and the leather is dyed by gentle agitation for approximately 10 minutes. There are also semicontinuous processes ((multimac) dyeing machine) for leather dyeing.			
Throughput:	A batch consists of between 450 and 900 kg of leather with a typical value of 680 kg. This batch size corresponds to between 40 and 80 grain leather sides, and between 100 and 200 suede leather sides, based on a weight of 11kg/side of grain leather and 4.5 kg/side of suede leather. The amount of formulated dyestuff used per batch is 6.8 kg for the grain leather sides, and 20 kg for the suede leather sides. Calculation for use rate per batch.annual amount of active colorant in the dyestuff solution used ranges from 200-2,500 kg/tannery, with an average use rate of 1,000 kg/tanneryThe total number of hides dyed at each facility typically averages 1,000 sides/day			
Number of sites:	315 tanneries in the United States, and 80% perform dyeing operations. Number of sites calculated based on PV and should not exceed 252 tanneries.			
Chemical concentration:	Amount of active chemical in the formulated dyestuff (% active chemical of interest) is typically 50% for powdered dyes and 15% for liquid dyes (most dyes used in leather dyeing are acid dyes)

EXTRACTION				
Parameter	Data			
Production, import, or use volume:	In 2002, the United States consumed 31 million pounds of cellulose ester film and sheet. In 1998 the United States produced approximately 619 thousand tons of polyester film (only 25% of polyester film consumed in the US is used in photographic industry).			
Process description:	Provides process descriptions for manufacture of photographic film and paper, formulation of photographic coating material, incorporation of coating onto the paper/film, and developing the paper/film after light exposure			
Chemical concentration:	Impurities are often added to the coating formulation to impart various photographic properties. These additives are often incorporated into the emulsion in very small concentrations, often the ppm or ppb range.

Study Citation:	U.S. EPA, (1994). Application of chemicals in enhanced oil recovery: steam stimulation, steam flooding, and polymer/surfactant flooding-generic scenario for estimating occupational exposures and environmental releases: Draft.			
HERO ID:	6385725			
Conditions of Use:	Enhanced Oil Recovery			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Enhanced oil recovery accounts for 10% of domestically produced oil (1992) with approximately 761,000 barrels/day produced			
Process description:	Polymer or surfactant formulated in enclosed continuously stirred tank reactor onsite, transferred to storage tank, then pumped into well with injection fluid using metered pumps. Steam stimulation involve steam injection followed by a waiting period before pumping. Steam flooding involves continuous steam injection.			
Throughput:	Successful enhanced oil recovery operation is considered one that recovers 20% as much oil as fluid injected (e.g., 20 barrels of oil per 100 barrels of injection fluid used). Default production rate of 5,300 barrels/site/day.			
Number of sites:	117 active enhanced oil recovery sites use steam stimulation and 26 active sites use a form of polymer flooding (1992)			
Chemical concentration:	Crosslinked polymers injected at concentrations of 1000 to 5000 ppm. Surfactants used at concentrations as low as 0.1% by weight

Study Citation:	U.S. EPA, (1994). Water treatment coagulants application - generic scenario for estimating occupational exposures and environmental releases: Draft.		
HERO ID:	6385760		
Conditions of Use:	Use of Water Treatment Products		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	12.9 billion lbs/yr of water treatment chemicals sold in 1988. 54% to treat municipal, utility, and institutional water. 34% to treat industrial water, 12% by residential and commercial markets. (pdf pg. 1)		
Process description:	Dry coagulants are fed gravimetrically or volumetrically to a mixing tank, slurry is decanted or pumped to point of application. Liquid coagulents are mixed in a tank with diluting water then pumped to point of application. (pdf pg. 3)		
Throughput:	180 gal per capita (pdf pg. 1)		
Number of sites:	59,000 public water treatment plants (pdf pg. 1)		
Chemical concentration:	concentrations are given for typical coagulents (formaldehyde was not listed)		
Comments:	Report is specific coagulents used in water treatment. The function of formaldehyde in the COU- Water Treatment Products, is unknown. Therefore, general information on coagulents is extracted and evaluated.		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	Report uses sound methods that are from frequently used sources, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States
	Metric 3: Applicability	Medium	The assessment is for an occupational scenario (use of water treatment products) within the scope of the risk evaluation but is not data specific to formaldehyde.
	Metric 4: Temporal Representativeness	Low	More than 20 years old.
	Metric 5: Sample Size	Medium	characterized by uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Assessment or report clearly documents results, methods, and assumptions. Data sources are generally described but not fully transparent.
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Medium	Uncertainty is not addressed. Variability is considered with different physical forms of the coagulents considered and different sizes of operation.
Overall Quality Determination		Medium	

Study Citation:	U.S. EPA, (2004). Additives in plastics processing (converting) - Generic scenario for estimating occupational exposures and environmental releases - Draft.
HERO ID:	6549571
Conditions of Use:	Additives in Plastics Processing (Converting into Finished Products)

EXTRACTION

Parameter	Data
Production, import, or use volume:	Table 2 presents the types of thermoplastic resins, common uses, and 2003 production volume.
Life cycle description:	The plastic manufacturing industry can be divided into four sections: polymer manufacturing, compounding, converting, and “in-house” manufacturing. This generic scenario will address converting operations. Polymer manufacturing will not be included in this scenario. Compounders produce masterbatches of plastic resins with specific properties by blending the polymer (resin), additives, fillers, and reinforcements. Converters receive the masterbatch of plastic resin from compounders and form finished plastic products. Compounding and converting may take place at the same facility (“in-house” manufacturing) or at separate facilities. This scenario assumes that compounding and converting take place at separate facilities; therefore, in-house manufacturing is not covered in this scenario.
Process description:	Various plastic processing operation descriptions are provided in Table 5, and a Process Diagram is provided on PDF pg. 10. More generally, polymer resin is received at the compounding sites from the resin manufacturer in the form of pellets. A compounding site blends the resin and additives to produce a masterbatch. The converting site then processes the masterbatch by shaping the plastic into the desired form for the final plastic product. The blending and forming may take place at the same facility (“in house” manufacturing) or separate facilities. As a conservative estimate, it is assumed that the compounding of the plastic resin and the converting of the resin into plastic products take place at separate facilities. Therefore, in-house manufacturing is not covered in this scenario. After shaping, finishing operations such as filing, grinding, sanding, polishing, painting, bonding, coating, engraving etc. are performed to complete the finished plastic product. This scenario covers the converting of plastic resins into finished products.
Throughput:	Daily use rate = amount of resin / # converting sites / days of operation x fraction of additive x fraction of chemical in additive
Number of sites:	Overall, there were 12,191 Plastic Product Manufacturing establishments in 2001. Table 1 provides Number of Establishments for subcategories of NAICS 3261 Plastic Product Manufacturing.
Chemical concentration:	Default values used to represent the weight fraction of various additives in plastic resin range from 0.001 - 0.5. These values are provided in Table 2 and Table 3.

HERO ID:	10369850			
Conditions of Use:	Processing, incorporation into product, paints and coatings			
EXTRACTION				
Parameter	Data			
Chemical concentration:	Formaldehyde is present in trace amounts in most raw materials used in paints, coatings, sealants and adhesives. Formaldehyde is in synthetic latex resins. Some raw materials can be manufactured with very low formaldehyde concentration, at less then 10 ppm, but it cannot be entirely eliminated. Formaldehyde will be present in amounts between 5-200 ppm for every pound of dispersion of synthetic latex polymers. Formaldehyde is also found in fluorescent pigments at concentrations below 50 ppm. Based on identified concentrations in raw materials, some formulators speculate certain final products could have concentrations in the range of 0.1–1% (1,000 ppm to 10,000 ppm) in final products. Formulators of these specialty products expect actual concentration is significantly less. (page 5 of 7)

Parameter	Data			
Process description:	Phenol-Formaldehyde (PF) Resins [PDF Pg. 9]A thermoset polymer manufactured by condensation of formaldehyde and phenol. PF resins are resistant to moisture and solvents and can withstand temperatures up to 200°C. They also have good electrical resistance and are noncombustible. PF resins are used in the building and construction industry for applications including insulation binder, wood-based products, and laminates. Other end uses include automobile applications (e.g., friction materials) and foundry binders.Methylene Diphenyl Diisocyanate (MDI) [PDF Pg. 9]Produced by reacting formaldehyde with aniline hydrochloride. The initial reaction yields diphenylmethane diamine, which reacts with additional formaldehyde to form trimmers, tetramers and higher oligomers. MDI is used in the production of polyurethane foams for use as insulation materials in construction and automotive applications. Foam applications can include appliances (e.g., refrigerators, freezers, and air conditioners), packaging for electronics, and transportation.Pentaerythritol (Penta) [PDF Pg. 10]Produced by reacting excess formaldehyde with acetaldehyde in an alkaline medium to produce a white crystalline powder. It is used in the production of alkyd resins, which are found in paints and product finishes for automobiles. It is also used to make polyol esters, an important ingredient of engine lubricants in heavy dutyapplications (e.g., airplane turbines and automobiles).Hexamethylenetetramine (HTMA) [PDF Pg. 10]A crystalline powder with a fused heterocyclic structure. HMTA is produced by reacting aqueous formaldehyde with ammonia. HTMA is primarily used as a crosslinking agent to cure resins which are used in foundry resins, friction materials, and other applications. It is also used in applications, such as rubber accelerators, explosives, and pharmaceuticals.

HERO ID:	5160116		
Conditions of Use:	Multiple COUs		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	Production volume of formaldehyde (37% by weight basis) in the United States in 1990, 1995, and 2000 were reported to be 7.5, 8.7, and 10.3 billion pounds, respectively (IARC 2006). From 1995 to 2000, formaldehyde production averaged an annual growth rate of 1.8% per year and was predicted to grow at a rate of 1.0% per year through 2004 (CMR 2001). The estimated total annual formaldehyde capacities in 1998 and 2001 were 11.3 and 12.5 billion pounds, respectively (C&EN 1998; CMR 2001). The annual growth rate of formaldehyde production from 2001 to 2006 was 0.9% per year, and was predicted to grow at a rate of 1.0% per year through 2010 (CMR 2007). The total annual capacity of formaldehyde production (37% solution basis) in the United States in 2007 was 11.9 billion pounds (SRI 2007). Table 4-1 shows capacity and production volumes for selected years between 1960 and 2007. AS of 2007, 3 manufacturers of FA were responsible for over 50% of the annual capacity for the US: Georgia-Pacific Chemicals LLC; Celanese Ltd. and Hexion Specialty Chemicals, Inc. Capacities and PV from 1960 to 2007 are in Table 4-1: Capacities start at 2,449 and go up to 11,900 from 1960 to 2007 with PVs going from 1,870 to 10,251 from 1960 to 2000. Table 4-2 provides each state with the number of facilities and min/max amount on site in pounds. 1999 import and export volumes were 82 and 21 million lbs respectively, and in 2000 they were 62 and 18 million lbs respectively. 2005 they were 21 and 27 million lbs respectively and in 2006 they were 22 and 31 million lbs respectively. FA consumption in the United States in 2005 and 2006 was reported as 10.24 and 10.50 billion pounds, respectively, and it is projected to be 10.93 billion pounds in 2010 (CMR 2007). Formaldehyde consumption in 1999 and 2000 was reported as 9.6 and 9.8 billion pounds, respectively (CMR 2001; IARC 2006). This was a slight decrease from the 11.3 and 11.6 billion pounds demand reported for formaldehyde in 1994 and 1995 (C&EN 1995). In 2001, it was reported that the fastest growing formaldehyde market, at about 5% per year, in the United States is in the production of acetylenic chemicals (butanediol), MDI, and acetal resins. Table 4-3 provides percentage distribution of FA production according to uses in the US with most recent in 2007 at 17% PF resins, 22% UF resins, 13% acetal resins, 9% Acetylenics (butanediol), 3% melamine resins, 10% in MDI, 5% pentaerythritol, 3% Hexamethylenetetramine, 3% fertilizer and 15% miscellaneous.		
Life cycle description:	The most extensive use of formaldehyde is in the manufacture of urea-formaldehyde, phenol-formaldehyde, melamine-formaldehyde resins, and polyacetal resins. Formaldehyde-based resins are used as adhesives and as impregnating resins in the manufacture of particle board, fiber board, plywood, furniture, and other wood products. Plywood is the largest market for phenol-formaldehyde resins, and particle board is the largest for urea-formaldehyde resins. These resins are also used for the production of curable moulding materials (appliances, electric controls, telephones, wiring services) and as raw materials for surface coatings and controlled release nitrogen fertilizers. Additionally, they are used in the textile, leather, rubber, and cement industries. Further uses are as binders for foundry sand, stonewool, and glasswool mats in insulating materials, abrasive paper, and brake linings. Polyacetal plastics produced by polymerization of formaldehyde are incorporated into automobiles to reduce weight and fuel consumption. They are also used in the manufacture of functional components of audio and video electronics equipment.		
Process description:	Because methanol is manufactured from synthesis gas, usually produced from methane, there have been extensive efforts to develop a one-step process that makes formaldehyde directly from methanol by partial oxidation. Although a successful commercial process has not been developed, a wide range of catalysts and oxidation conditions have been studied. Following World War II, approximately 20% of the production volume in the United States was manufactured by vapor phase, non-catalytic oxidation of propane and butanes. This nonselective oxidation process produces a variety of coproducts that require a costly and complex separation system, and therefore, the methanol process is preferred. Formaldehyde is also produced in solid form as its cyclic trimer, trioxane, and as its polymer, paraformaldehyde. As a readily available source of formaldehyde for certain applications, paraformaldehyde is prepared commercially by the concentration of aqueous formaldehyde solutions under vacuum in the presence of small amounts of formic acid and metal formates. Trioxane is prepared commercially by strong acid-catalyzed condensation of formaldehyde in a continuous process. Available information indicates that paraformaldehyde is produced in the United States by three companies and trioxane is produced by two companies.		
Number of sites:	Source of number of facilities that produce, process or use FA on Table 4-2 is from TRI data.

HERO ID:	1318521			
Conditions of Use:	Multiple			
EXTRACTION				
Parameter	Data			
Process description:	The Bureau of Engraving and Printing is responsible for the production of all United States currency. The printing of the currency involves single pass intaglio printing. The notes are printed on a special currency paper that contains a melamine-formaldehyde resin to impart wet strength to the finished product. Two inks are used, black and green, with green applied first, and then after about a 48 hour curing period the black or face is applied. The inks cure by oxidative polymerization. The inks are composed of three primary parts: the vehicle containing resins and solvents; the color which contains metal pigments or oxides; and ink driers (metal soaps) which may contain cobalt, lead, or manganese compounds-for example lead octoate. None of the aldehydes identified by the bureau are listed as an ink constituent by any of the ink manufacturers.Loads of currency are brought into the mechanical examination areas from vaults after a 24 to 48 hour holding period after printing has been completed. The loads, two stacks of 10,000-32 subject sheets, are manually opened and separated on a vibrating table, and shingled out onto the currency feeder as needed to maintain a continuous flow of the sheets through the mechanical examining unit and past the examiners. During this process the sheets are cut and trimmed to two 16 subject sheets and defective sheets are removed. The examining units have four examiners who examine the face (front) and backs of the currency sheets. This is the first opportunity for separation of the individual sheets after the currency has been printed. The loads are locked down tightly during storage and must be broken apart manually after removal of the locking strap. The temperature and relative humidity was closely regulated in both the printing and mechanical examining areas. Temperatures were maintained around 72 to 74 Fahrenheit and the relative humidity was held between 45 and 55%.			
Throughput:	Regular production currency examination ranges from 35 to 40 thousand 32 subject sheets per work shift.			
Number of sites:	1			
Comments:	The source of the formaldehyde is most likely due to the presence of a melamine-formaldehyde resin used in the currency paper. The work conducted by the bureau concerning aldehyde levels associated with the various test currency samples demonstrated little variation in formaldehyde concentrations among regular production currency, test currency printed with the test inks, blind embossed currency paper (no ink but run through the press), and unprocessed blank currency paper.

EXTRACTION	
Parameter	Data
Process description:	Coils of steel come into the rolling mill staging area from the pickling lines west of the rolling mill area. Steel enters the five-stand tandem mill with gauges of .080-.250 inch and, under the extreme roll pressures applied by the mills is cold reduced into longer thinner sheets of steel with gauges of .011-.101 inches. The reversing mill also cold reduces the steel as well as tempering the steel. Lighter gauges are generally run on the tandem mill and heavier gauges on the reversing mill. A coolant is applied to the coil steel from coolant nozzles aimed at the steel as it enters the rolls of each mill stand. A continuous flow of coolant cascades over the sheet during mill operation. The action of the rolls on the mill, the movement of the steel coil, and the spray of the coolant from the coolant supply nozzles result in generation of a continuous mist during mill operation. The gauge reduction being taken on the steel, the gauge of the feed stock, and the mill speeds affect the build up of heat in the mills and the amount of mist and vapors coming off of the mills. The work stations for the mills are located at control panels along the east side of the tandem mill and the west side of the reversing mill. Workers generally stand back from the tandem mills during their operation except to make adjustments, check controls, and at the start and end of a coil pass through the mill. (3/24)

EXTRACTION	
Parameter	Data
Process description:	Beet sugar production, as indicated above, is a seasonal operation. In the early to late fall the beets are harvested and transported by truck to the plant where they are either stockpiled on the ground or dumped directly from the trucks into wet hoppers. Beets enter the factory via a water flume and go through several debris removing devices prior to washing. After cleaning, the /, beets are sliced into pieces called "cassettes". The cassettes are conveyed into the bottom of a large inclined cylindrical vessel called the diffuser. Hot water, flowing across the cassettes, is used to extract the sugar via osmosis. The sugar solution leaves the diffuser in the form of "raw juice". The processed cassettes (beet pulp), now devoid of most of the sugar, are dried in a large coal fired rotary drying drum, then are made into pellets for use as livestock feed.After leaving the diffusers, the raw juice is mixed with milk of lime and carbon dioxide (CO2) .(produced in the lime kiln from the oxidation of CaC03 using coke as a fuel source) in carbonation vessels to precipitate impurities and non-sugars from the juice. The juice is filtered several times to remove solidified impurities. The "thin juice" as it is now called is piped into evaporators, which thicken the mixture by evaporating excess water. The steam required for the evaporation process is provided by coal-fired boilers. The resulting thickened juice is boiled in vacuum pans and seeded with sugar crystals to initiate the crystallization process. The mixture is then transferred to centrifugals where the sugar crystals are separated from the remaining syrup (beet morasses). After drying, the sugar crystals are sorted by crystal size through screens, and stored in bulk bins (concrete silos or Weibul bins) prior to being bagged or bulk loaded into railroad cars.
Throughput:	Produces 595 tons of sugar are produced each day of the 180 day campaign period

Parameter	Data			
Process description:	Monkey cadavers preserved in formalin are used for identification of anatomical parts. By the college policy, primate specimens are rinsed in Caro-Safe before teachers or students are allowed to work with the primates. Caro-Safe is a holding fluid containing ethylene glycol. Holding fluids are solutions used to store or rinse preserved materials. The reason for rinsing or treating formalin fixed specimens with holding fluids is to remove any excess formalin.			
Number of sites:	1			
Chemical concentration:	Formalin is a solution of formaldehyde gas in water and generally contains 37% formaldehyde gas of the equivalent of 37 grams of gas in 100 ml of water.

Life cycle description:	Reactant: Phenol-Formaldehyde resin production.			
Process description:	Decorative laminate built of several layers of paper sheets impregnated with PFR (phenol and formaldehyde resin) and resol resins based on phenol and formaldehyde. The outer layer paper was impregnated with melamine-formaldehyde resins. In varnishing machines, paper from rolls were passed through a resin bath which was filled from a closed system. The impregnated paper was then moved through a drying zone and subsequently cut into sheets of appropriate size. Next the impregnated sheets of paper were stacked to the desired laminate thickness, a step done manually, followed by curing which took place in a press at a certain temperature and pressure for a specified time. Finally the post-lamination processing of the product involved sawing, cutting and inspection steps.

Life cycle description:	manufactured on site, used on site and also sold to customers			
Process description:	Formox Metal Oxide CatalystMethanol is delivered by truck and stored in bulk storage tank. Methanol is vaporized with filtered air. The methanol/air mixture enters one of two large parallel packed-tube reactors and oxidized to formaldehyde. The formaldehyde vapors pass through an aftercooler and are absorbed in water in a single absorber. The formaldehyde solution is stored in a bulk storage tank prior to transfer to an ion-exchange purification system which removed formic acid. the final product is sent to bulk storage and shipped out by tank trucks. Heat from the reactor is recovered using a heat exchanger that uses Dowtherm as a heat transfer solution which is vaporized after creating steam in a low-pressure boiler. Silver CatalystMethanol is pumped from storage tanks. Methanol is vaporized with filtered air. The methanol/air mixture is fed through headers to reactors that contain a silver catalyst for conversion into formaldehyde. Heat from the reactor is recovered in a steam generator. The cooled formaldehyde vapors pass through an absorber column creating a formaldehyde solution at a concentration of 40%. A 60 plate tray stripper is used to concentrate the formaldehyde to 46%. The formaldehyde solution is stored in a bulk storage tank then used on site.

Study Citation:	Anonymous, (1970). Formox formaldehyde process. Chemical & Process Engineering 151(4):100-101.			
HERO ID:	5956682			
Conditions of Use:	manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	By 1970, the process was used in approximately 25 plants with a total capacity of about 750,000 t/a calculated as 37% formaldehyde.			
Process description:	The Formox process produces formaldehyde utilizing a molybdenum-based catalyst for the direct oxidation of methanol to formaldehyde. The reaction for the process is CH3OH + 1/2O2 = HCHO + H2O. Methanol is metered to the process, mixed with air, and vaporized in the vaporizer. The vapor mixture enters a fixed-bed tube reactor, which is charged to a specified depth with the metal oxide catalyst. A ratio of methanol to air in the range 5-8 moles methanol per 100 moles of air is used to maintain the desired oxidation atmosphere. The reaction temperature increases as the gas mixture enters the catalyst space and rises very rapidly to a point of maximum reaction in the catalyst mass. After the reaction has reached its peak, the product gases are cooled rapidly until they approach the temperature of the heat transfer medium prior to leaving the catalyst tubes. The product gases leave the reactor and pass to a gas cooler which is operated as a waste heat boiler. Here the gases are cooled before passing to a stainless steel absorption tower. Water is fed into the top of the absorption tower counter-current to the gas flow at a rate which maintains a desired formaldehyde concentration of up to 55% at the tower base. The heat of solution of formaldehyde and heat remaining in the reaction gases is removed by appropriate water cooling.			
Number of sites:	25			
Chemical concentration:	The Formox process produced a product concentration of 55% without additional concentration stages. The process features a high conversion making the recovery of methanol from the final product unnecessary.

Parameter	Data			
Process description:	Certain-Teed Products, Inc, processes felt and fibrous glass asphaltshingles and rolled roofing products. The request involves the production of these products. The rolled felt is fed in a continuous ribbon through accumulation loops, makes two 90 degree turns, and enters the saturator; alternatively the feed roll can be put directly in line with the saturator. In the saturator, hot petroleum asphalt of approximately 400 oF is sprayed and flowed onto the felt. As the felt exits the saturator, it is completely saturated with the asphalt. The saturator is enclosed and is kept under negative pressure. The saturated felt then passes into the coater. From this point on, the felt and the fibrous glass are treated the same (the fibrous glass passes through the accumulator loops and saturator, however, no asphalt is applied to the fibrous glass in the saturator). In the coater, hot asphalt that has been thickened with limestone is flowed on the top side of the felt or fiberglass. The coater is enclosed and is provided with local exhaust ventilation. The asphalt is then spread with rollers and passes to the press area where the slate granules are dropped on the surface and pressedinto the asphalt. After the granules have been pressed into the asphalt, a mixture of talc and sand is applied to the back side of the material to prevent sticking. The material passes through a water spray for cooling and another set of cooling and accumulation loops. From there, it passes through an operation called "Seal Down" where a thin stream of asphalt is applied to the shingles. Ithen proceeds to the cutter, where the individual shingles are cut from the continuous ribbon. The shingles are automatically stacked, wrapped, and proceed to the warehouse where they are placed on pallets and stored.

Process description:	This plant makes paper from pulp and makes carbonless paper by applying the appropriate coatings to the paper. The paper itself is produced in a continuous sheet from a pulp slurry. There are two types of coating applied to the paper. One is CF coating which is applied to the front of the second and subsequent sheets. The other is a CB coating which is applied to the back of the first sheet and subsequent sheets. Hence, in a three sheet form, the first sheet would have a CB coating applied to the back of the sheet. The second sheet would have a CF coating on the front and a CB coating on the back and the third sheet would have a CF coating on the front and a CB on the back.Changes were recently made in the coating application process. The CF coating is now applied as the paper exits the paper machine. The coating is applied, it passes through a dryer and is wound on a roll. The CB is applied in a separate plant area where previously both the CF and CB were applied. The CB is applied to the paper, the paper passes through a series of dryers and is rewound on a roll. The CF and CB coating are prepared in the coater prep area. The CF coating consists basically of a phenolic resin. It also contains water, dispersant, starch, blade lubricant, and polyvinyl alcohol. The phenolic resins had previously been cooked in the coater prep area. A recent change has been to purchase the phenolic resin already prepared. This change reduced the coater prep personnel exposure to phenol. The CB coating is composed of small urethane capsules that contain a dye, latex, starch, butyl biphenol, petroleum solvent and diethylene triamine.Carbonless paper is such that when pressure is applied with a pencil the capsules in the CB coating break and the dye is released. The dye then reacts with the phenol in the CF coating and a color is produced.

EXTRACTION

Parameter	Data
Process description:	Asphalt Roofing Manufacturing [PDF Pg. 3-4]Although asphalt is used to make a number of different roofing products — including shingles, surfaced and smooth roll roofing, modified bitumen membranes and asphalt-saturated felt —the manufacturing process generally involves the same sequence of steps:a. coating: a mixture of a coating asphalt and a mineral stabilizer is used to coat fiberglass mat; in the case of products using organic felts, the felt is first subjected to a saturation process involving a low softening point asphalt;b. mineral surfacing such as colored granules may be embedded in the surface of the filled asphalt;c. cooling and drying: water-cooling and/or air-drying procedures are used to bring the product to ambient temperatures;d. product finishing: for certain products, formatting the designated asphalt roofing products by embossing, cutting, or painting; ande. packaging.First, the fiberglass mat consists of fibers bonded with a urea-formaldehyde (UF) binder, and some off-gassing of formaldehyde can occur from heating when hot asphalt contacts the fiberglass mat and before the mat is completely encapsulated during the coating step. Second, formaldehyde has been found in emissions from heated storage tanks supplying the coating operation.Asphalt Processing [PDF Pg. 5]Some asphalt roofing product manufacturers also process oxidized asphalt, one of the asphalt types used in roofing manufacturing. Roofing manufacturers can also obtain oxidized asphalt from independent asphalt processors or refineries.Oxidized asphalt is produced by blowing air through hot petroleum residuum, known as roofing flux, made from atmospheric or vacuum distillation, solvent extraction or other refining processes. Roofing flux is typically pumped from a heated tank and/or through a direct-fired or hot oil-heated noncontact heater into reaction vessels called blow stills (sometimes called oxidizers or convertors). Air is injected into the roofing flux in the blow still through perforated pipes. Some of the oxygen in the pumped air is consumed by the reaction of air with the roofing flux. Emissions from blow stills are treated in a variety of separation devices to remove condensed or entrained process oil, and then are oxidized in a thermal oxidizer operating at temperatures that exceed 1200° F (649° C). According to EPA, emissions from all blow stills, whether they are major or area sources of HAPs, are controlled by thermal oxidizers.Fiberglass Mat Manufacturing [PDG Pg. 6-7]Some asphalt roofing product manufacturers produce the fiberglass mat used in the roofing manufacturing operation. Most, if not all, of these operations use urea-formaldehyde-based (UF-based) resins to bond glass fibers together, which can be used as a substrate for many roofing products. The typical process steps are the following:a. Glass fibers are mixed together with water and emulsifiers in mixing vats to form a slurry of fibers and water.b. The glass fiber slurry is pumped to a mat-forming machine, where it is dispensed over a moving screen belt.c. The mat is carried beneath a binder saturator, where binder solution is uniformly applied onto the surface of the mat.d. The screen passes over a vacuum, which draws away the excess binder solution for re-use.e. The mat of fibers and binder passes into drying and curing ovens that use heated air to remove excess moisture and set (i.e., cure) the binder.f. The mat is then cooled, trimmed, wound and packaged to product specifications.

EXTRACTION				
Parameter		Data		
Production, import, or use volume:		between 6.43 billion pounds and 8.11 billion pounds for 1990, 1991, and the period 1993–1995. 140 million pounds of formaldehyde were imported into the US in 1997. Additional historical data are also included. 23% of formaldehyde is used to make urea-formaldehyde resins, most of which is used to make particle board products. the study provides a more comprehensive listing of uses of formaldehyde		
Life cycle description:		reactant		
Process description:		Two primary methods of manufacturing formaldehyde from methanol are used today. The first uses silver as a metal catalyst in its reactions. In earlier years, facilities used a copper catalyst in this process. The simultaneous reactions involved in the metal catalyst process occur at essentially atmospheric pressure and 600–650.The second method uses a metal oxide catalyst. All of the formaldehyde is produced from an exothermic reaction occurring at atmospheric pressure and 300–400 EC. The patent for formaldehyde production using a vanadium pentoxide catalyst was issued in 1921. Although the patent for an iron oxidemolybdenum oxide catalyst was issued in 1933, the first commercial facility did not begin operating until 1952 .		
Number of sites:		As of 1998, there are 3 manufacturers that represented 50% pf annual capacity (Georgia-pacific resins; Hoechst Celanese Corp, and Borden, inc.. a more comprehensive list is provided in the study.

HERO ID:	5971795			
Conditions of Use:	Adhesive in the manufacture of plywood panels			
EXTRACTION				
Parameter		Data		
Process description:		Veneer drying, which leads to formaldehyde emission, is an important stage in the manufacturing of wood-based panel products such as plywood and laminated veneer lumber (LVL). The drying process accounts for some 70% of the thermal energy consumed in plywood production and approximately 60% of the mill’s total energy requirement. Although drying temperatures of between 90 and 160 deg C may be considered normal, increased temperatures are being used to reduce the overall drying time and increase capacity.		
Chemical concentration:		Urea formaldehyde (UF) resin with 55% solid content was used as adhesive in the manufacture of plywood panels.

EXTRACTION				
Parameter	Data			
Process description:	The plant manufactures approximately 15 fibrous glass product groups (about 500 individual products which utilize approximately 27 individual chemical substances) from conventional glass making raw materials such as borosilicate and low alkaline silicate glasses. The fibrous glass produced by melting and fiberizing silicate glass is called the pot marble process. This is similar to the spin process seen with the manufacture of mineral wool. Once the glass marbles are melted, the fiber strands are pulled through to the gas burners and directed through the forming tubes. The glass fibers are sprayed at the binder header with a phenol-formaldehyde resin. Silicon, oil, dyes, pigments and adhesives may be used in the process. The sprayed glass is collected at the U-Chute on the collection chain after which the material is passed through the searing roll platform and the curing ovens. The glass is then cooled, cut and packaged.

Study Citation:	Bello, A., Xue, Y., Gore, R., Woskie, S., Bello, D. (2019). Assessment and control of exposures to polymeric methylene diphenyl diisocyanate (pMDI) in spray polyurethane foam applicators. International Journal of Hygiene and Environmental Health 222(5):804-815.			
HERO ID:	6134670			
Conditions of Use:	Spray polyurethane foam			
EXTRACTION				
Parameter	Data			
Process description:	The SPF foam is produced from the chemical reaction of two components, commonly referred as part A and part B, which are supplied at an approximate ratio of 1:1 to a spray gun nozzle. Part A is comprised of polymeric methylene diphenyl diisocyanate (pMDI), a mixture of the 4,4’-methylene diphenyl diisocyanate (4,4’-MDI), other MDI isomers (2,4’ - and 2,2’-MDI) and higher oligomers of MDI (such as three ring, and four ring structures). Part B is a mixture of polyols, amine catalysts, blowing agents, flame retardants, solvents, and other proprietary additives (Bello et al., 2018; Marlow et al., 2014; Lesage et al., 2007). The exothermic reaction between the isocyanates in part A and polyols in part B is accelerated by the amine catalysts and other additives in part B. Polymerization reaction starts immediately upon mixing of the two components. The foam expands, solidifies and cures within 2–48 h postapplication, depending on the product type. In this paper, the term isocyanates has been used exclusively to mean pMDI or any of its components, such as MDI isomers, unless otherwise specified.			
Comments:	Study does not mention formaldehyde but has information on the condition of use for spray polyurethane foam application.

EXTRACTION

Parameter	Data
Process description:	Plant G Foundry Products Two foundry processes were studied in this operation: Coremaking and metal pouring. Both processes were conducted as small batch operations. The first process studied was coremaking. Cores are made to provide interior areas within castings. Two types of core materials were used. The first mixture was of the following blend: Sand - 100 parts Phenol-formaldehyde resin - 2 parts Ammonium chloride catalyst in aqueous media - 0.4 part. These items were blended by machine. The technician then checked the mixture for the proper consistency. Since the resin-catalyst system will "set" with time, the mixture was used immediately. The coremaking machine was an air-operated press which heated molding materials to temperatures in excess of 5000 F. The mixture was blown under pressure into the mold of the press. It was then placed under pressure and heated to 4500 F for 1 minute. At the end of 1 minute, the molded cores were removed from the press and allowed to cool. At this point, the resin at the surface of the core was cured. Excess heat retained in the core was dissipated; however, much of it tended to hasten curing of the core's interior. Usually, cooling of a 1-inch by 1-inch by 3-inch core required about 10 to 15 minutes. Coremaking, using this equipment, was conveniently conducted for about 1 hour. A second coremaking was conducted using a slightly different mixture of materials. They included: Sand - 100 parts Furfuryl alcohol-formaldehyde resin - 2 parts Ammonium chloride catalyst in aqueous media - 0.4 part. Again, these items were mixed, molded, and cooled under essentially the same conditions as the phenol-formaldehyde resin mixture. The two resins selected represented the two most commonly used binding resins used in the foundry industry which have both formaldehyde and chloride ions present. The specific resin catalyst systems used were manufactured by the company visited and reflect their particular resin-catalyst formulation. A second process studied was the metal-pouring area. Molten iron was cast in 2,000-gram molds. The mold was a common step-type mold used to determine the qualities of the binders developed by this company. Two molds were prepared which had used the phenol formaldehyde, ammonium chloride binder system. Iron was melted and heated to approximately 2,900° F. It was then poured into a preheated ladle, manually moved to the mold, and poured at 2,700° F. The outer casing of the mold was graphite, a substance that was understood to be inert during the pouring. Once poured, the core was allowed to cool for at least 30 minutes in the mold. The casting was then opened and allowed to air-cool for about 8 hours, at which time it could be handled without protective equipment. Two pourings were made with the phenol-formaldehyde resin, ammonium chloride catalyst mix. Later, the furfuryl alcohol-formaldehyde resin, ammonium chloride catalyst mix was used in two pourings of iron. The process was essentially the same as that discussed for phenol-formaldehyde resin mixes. Plant H. Foundry Products - Full scale. The process in question was the production of ferrous metal castings, using shell molds. The molds were formed using heat and a catalyst to cure the resin/sand mixture. Once cooled and hardened, metal was poured into the molds, allowed to cool, and then removed from the mold. The molding department received a molding sand which was premixed. The components of this mixture included sand, phenol formaldehyde resin, and hexamethylenetetramine. The hexamethylenetetramine was used as a high-temperature catalyst for the curing of the resin. The sand mixture was forced around a metal pattern, pressed into place, and then heated to about 4000 F. The total time involved in this process was about 1-1/2 minutes. The mold was then removed, broken in half, and both halves glued together. The result was a completed mold commonly called a "shell mold" in this facility. Molds were moved into the pouring area. Some molds were simply placed in a sand pit, located centrally in the facility, and poured. No control over effluents from pouring were in use. However, this method was used only in small-job pouring of molds of this type. Castings were cooled in the same area. In a second-type pouring, a cooling range was used. Metal was poured under a slotted hood and then the castings were moved into the cooling range which was ventilated. Because of the smaller size of the castings, cooling usually required only a few hours. Castings were then manually broken out or shaken out of the molds and moved to the finishing area for welding, grinding, cleaning, etc. The whole process, from mold making to being ready for finishing, was accomplished in 2 days.

Parameter	Data
Process description:	Plant A Dye Auxiliaries (resin) ProductionThe process under investigation was the production. of a resin that was used in the dyeing of various paper products. The process involved a relatively simple reaction whereby an amine formaldehyde resin was produced.In this facility, the resin was produced in 3.5-ton batches. The time needed to produce the finished resin was about 24 hours.Materials were either piped directly into the reaction vessel (formaldehyde, water) or were manually added to the reaction vessel through a small hatch (dicyanamide, ammonium chloride, caustic soda). The step of adding these substances required two employees and about 1/2 hour per batch.Once the major components were placed into the reaction vessel, mixing, heating, and refluxing took place. This continued for at least 6 hours and usually for about 24 hours. Samples were taken at various times to determine the relative completion of the reaction. Once the laboratory was satisfied with the product, it wasthen ready for packing. Occasionally, where product specification dictated, water and caustic soda were added to the mixing batch.The finished product was packed into drums, each containing 400 pounds of the finished resin. This step was done manually by one employee. The resin was piped by gravity flow into a canopy hood, where it was dropped into the drum. The drums were sealed andmoved into the warehousing area. The process required about 2 hours per batch.Plant B Dye ManufactureThe company surveyed was a producer of dyes and auxiliary chemicals for textiles, paper, and leather products; flavors and dyes for food products; colors for plastics; and other industrially oriented organic chemicals. The plant sampled, was one of the major facilities of several owned by the company. Primarily, it produced dyes that are used in the textile and food industry.a. Yellow-Orange Dye Production - The yellow-orange dye which was produced was essentially based on the aniline molecule, with various substitutions used to develop the proper color in the dye material. Part of this substitution process required that the amino group be blocked off from reacting while other substitutions were occurring. This was the role of the formaldehyde in this process. Later in the process, muriatic acid was used to remove this blocking group and allow another chemical rearrangement to occur. Initially, two tanks were used. In one was mixed formaldehyde, sodium bisulfite, and sulfuric acid. The second tank was filled with an aniline mixture. Both were then dropped into a third tank where they were mixed. An exothermic reaction occurred and to slow the reaction, ice was added and the reaction mixture was cooled to nearly 0° C. The mixture was made alkaline by the addition of caustic soda and was then filtered. The resulting filter cake was reslurred, using water and muriatic acid in excess. Again, the mixture was filtered, and the resulting filter cake reslurred. Muriatic acid and phenol were added and the solution was then refiltered. Once this third filtration was completed, the filter cake was dried in steam~heated ovens, milled, mixed to specifications, and packaged into drums.The process was a large-volume one where amounts of various materials added sometimes reached into the several-ton category. Most steps in the process required the manual addition of materials to the reaction vessels. To produce this dye, a single batch required up to 4 days to complete the steps necessary to be ready for drying in the oven. Once ready for drying, the dye material was placed into the ovens for several days to ensure complete drying. The material was then stored in drums until sufficient customer demand or warehousing requirements indicated the need for finalmilling and mixing to customer specifications.b. Cyanide Liquor Waste Water Treatment - Another dyestuff produced at this plant required the use of large amounts of cyanide-containing materials. As a result of liquor removal, large amounts of unreacted cyanides were found in the liquor, which presented a serious waste-water removal problem. To reduce the level of 'cyanide in the wastewater to an acceptable level, the cyanide was bound up in a polymer with formaldehyde.To help the reaction occur to sufficient completeness for wastewater requirements, muriatic acid was added to catalyze the reaction.The reaction was very quick and required little control. All of the operations were closed vessels with only one open point, where the effluents were dumped into a holding pit, awaiting removal to the disposal point. The addition of chemicals was done by piping needed materials directly into the reaction vessel. No manual work was conducted. Throughput: Plant A Dye Auxiliaries (resin) ProductionIn this facility, the resin was produced in 3.5-ton batches. The time needed to produce the finished resin was about 24 hours.

EXTRACTION				
Parameter	Data			
Process description:	Plant C Fertilizer productionThe product produced was known as 10-6-4 with 60 percent organic material urea-formaldehyde fertilizer. In its mixing process, potassium chloride and urea-formaldehyde were mixed in an acid condition. To produce this fertilizer, several steps had to be conducted. Initially, the dry ingredients were placed into a hopper where they were fed into a conveyor at a specified rate based on the specifications of the mix. These ingredients included potash, phosphorus-containing material, limestone, and anhydrous ammonia. Once mixed, the dry materials were ground up and further mixed. They were then placed into an ammoniator. Here, the dry mixture was coated with a mixture of urea-formaldehyde resin (in liquid form) and sulfuric acid.At this point, the reaction occurred which converted the mixture of products into a product that will allow a balanced discharge of nutrients once placed on the lawn or garden. The reaction was exothermic. creating heat of about 200° F in the mixture. Because of the water and liquid present, the fertilizer took a granular form.Before the fertilizer was ready for packing, it first had to be dried to remove the available liquids present, then cooled to approximately room temperature, and sized to the proper granular size for proper application characteristics in the home or-garden.This operation was conducted in two large rotary drums. The dryer was oil-fired to temperatures over 2000 F. Once through the dryer, the fertilizer was moved into the cooler where it was subjected to a flow of cool air. The fertilizer was then sized and either reground to the proper size (in the case of too-coarse granules) or reintroduced into the ammoniator for agglomeration (in the case of too-fine granules).Once delivered from the sizing area, the finished fertilizer was moved into bulk storage. From start to finish, the process was rapid, with a total residence time of 30 minutes or less.

EXTRACTION	
Parameter	Data
Process description:	Plant D, Textile Finishing The process of interest for this survey was the resin-finishing operation. One of the more commonly used finishes was glyoxal urea-formaldehyde, a resin with good qualities for crease prevention. The process to resin-finish textiles was a relatively simple one, but one that had several steps. Initially, the cloth was washed, bleached, dyed, and dried before it was ready for resin finishing. The cloth, usually in a roll, was unraveled into a scray. This unraveling prevented sheaves and rollers in the frames farther down the process line from pulling too hard on the cloth, possibly causing danger to the product. It was then ready for resin treating. On a mezzanine above the finishing frame floor were vessels that were used to mix the resin solution to the specifications required by the intended use of the cloth. Typically, 200- to 250-gallon batches of glyoxal resin, and appropriate amounts of magnesium chloride, water, softeners, hand builders, and other substances were used to complete the mixture. This solution was mixed and then gravity-fed to the pad bath area as needed. The cloth was drawn through the pad bath containing the resin solution. The pickup of resins was about 70 to 80 percent of the weight of the cloth. Once through the pad bath, the cloth was squeezed between rollers to eliminate a large amount of the water. Cloth with 30 percent resin weight was started on a process where it was dried and stretched, and the resin cured. Initially, the cloth was drawn through a predryer. Here, temperatures were sufficiently hot to drive off the water found in the resin mixture, but not so hot as to change the resin mixture. The water acted as a carrier in this process but did not have an actual part in the finished product. The next step was more drying, but this time while the cloth was being stretched. By the end of this step, most of the water was removed, but nothing had occurred to the resin. Temperatures in the dryer typically reached 250 0 F. The last major step in finishing was in the cure oven. Here, the temperatures were elevated to those needed to cure or harden the resin with the catalyst present. These approached 300 0 F or higher, as needed. Once curing was completed, the cloth was sent to inspection and on to warehousing for shipment or storage. In this facility, the predryer, dryer, and cure oven were ventilated through enclosures of the equipment. The remaining areas were essentially unventilated, releasing vapors and mists into nearby work environments. Plant E Textile Finishing The first step in the finishing of knit goods at this plant was the mixing of the resin and catalyst. A mezzanine existed in the center of the finishing room area where the resin, in an aqueous form, was gravity-drawn into mixing vessels. Magnesium chloride was added manually with buckets to the specifications of the mix. Softeners and wetting agents were added as needed. The batch, about 200 gallons, was then mixed and, within several minutes, was ready for use. The medium of the resin-catalyst mixture was aqueous. With the addition of the catalyst, the pH of the mixture became slightly acidic with a temperature that was nearly ambient. No pH adjustments were made. The typical mixes of the resins were from about 200 pounds resin/40 pounds catalyst to 100 gallons of water to about 50 pounds resin/10 pounds catalyst to 100 gallons of water. Once the resin-catalyst mixture was produced, it was used on either one of two finishing lines: tubular knit finishing and open knit finishing. Both employed different finishing techniques, hence they require separate discussions. In the tubular finishing operation, the knit goods were moved manually to the pad bath area where the knit goods were drawn through a series of stretchers and exposed to steam. Cloth temperatures were between 900 F and 1050 F at this point. The cloth was then drawn through the resin bath to about 80 percent w/w wet pickup. After the resin bath, the cloth was introduced into the predryer stage where some of the aqueous solution was removed. Temperatures in the predryer averaged about 250 0 F. Once predried, the cloth was calendered, stretched, and steamed to final dimensions. Then the cloth was introduced into the loop dryer-curing ovens. At this point, temperatures reached over 300 0 F for curing of the resin. Again, the residence time was short but was longer than in the drying stages, about 4 minutes. The process was enclosed and ventilated. In this process, with the combination of heat and residence time, the lubricants commonly used in knitting evolved from the knitted cloth as a smoke which was visible in the curing oven. After the completion of curing, the cloth was ready for inspection and movement into the warehousing area. The second method for finishing knitted cloth used at this plant was a process known as open-width finishing. Since knitted cloth is produced in a tubular form, the cloth had first to be cut lengthwise and stretched, forming the more normal cloth appearance. The cloth then entered the finishing line. Initially, the cloth was drawn through the pad box as was the case in the tubular knit process. However, once this was completed, the cloth entered a machine that combined the predryer, dryer, and curing oven into one continuous step. At the end, the cloth was ready for inspection and removed to the warehouse. The machine was commonly known as a tenter frame or more simply "frame." The temperature gradient in the one-step process began at approximately 2500 F and rose about 1000 F before the curing was completed. Although these temperatures were somewhat higher than those found in the tubular finishing process, the residence time was reduced by one-half to one-quarter of that required in the tubular finishing.

Process description:	Plant F Hospital burn centerThe product of this process was a gel pad which was used in the treatment of burn victims. Because of the plastic properties of the gel, it was exceptional in allowing burn victims to rest body weight on sensitive tissue comfortably without hindering thehealing process. Because the gel pad was not presently availablefrom commercial sources, this laboratory was charged with the production of these pads for use in the burn ward of the hospital.The process required to make this product was very much batch-oriented. A typical batch yielded one large pad and several small pads and required about 5 days of processing. Approximately 3,500 ml of deionized water was placed into a stainless steel container v/hich was placed into a hot water bath set to approximately 90° C. Before the deionized water was heated significantly, 400 grams of polyvinyl alcohol were added, and themixture was slowly stirred. When the initial charge of polyvinylalcohol was almost completely dissolved, another 500 grams of polyvinyl was added. This charge was added to 1,600 ml of cold water and was then added to the heated mixture slowly while it was being stirred. The mixture was stirred for 2 to 3 hours while it was heated. When the solution became clear, the mixture was ready for the next step. Up to this point, one person was required. Most of the operations were essentially monitored. No environmental controls were used. The hot, clear mixture vias then taken off the water bath and moved into a hood. With stirring, 4 pints of formalin solution (37 percent formaldehyde), 24 ml of hydrochloric acid, and food coloring were added. This was done as quickly as possible with a fast stirring rate. Once these items were added and the food color appeared to be evenly mixed, the mixture was placed into a large, flat-bottomed, olive -oil-coated pan. The pan was covered with plate glass and placed into an oven se~ to 71° C. The gel pad was cured for 2 to 2-1/2 hours. Upon removal, the pad was placed into a large pan containing cool tap water. Water from the tap was circulated through the pan continuously for 24 hours.Once the pad had been rinsed for 24 hours, it was moved to another larger rinsing pan where water containing 3 percent urea in propylene glycol was washed over the pad. This was conducted for 3 days. The pads were then dried, cut to size as needed, and heat-sealed in polyethylene bags.

Process description:	Formaldehyde vapor has been used as a disinfecting agent for mechanical ventilators. In the original method from 1960s, the ventilator circuit was exposed for 8 hours to vapor from a solution of formaldehyde heated in the humidifier. The authors used an experimental technique in which the has from a separate generator was circulated in a cabinet in which the ventilator was placed in open circuit. The system used for the ‘cabinet technique’ was designed by Vickers (Medical) Ltd for the disinfection of equipment which cannot be subjected to conventional sterilization techniques. The metal disinfection cabinet used in the experiments had an internal diameter of about 1 m3 and was connected by flexible plastic tubing to a gas generating console. Each stage of the operation was automatically controlled and timed. Twenty ml of an appropriate solution of formaldehyde was totally evaporated in the generator and the gas was recirculated for a preselected time through the cabinet and ventilator. There was no connection between the inspiratory and expiratory ports of the ventilator during these experiments and the humidifier was empty. There was no bag at the patient Y-piece and formaldehyde vapor entered the ventilator both at the inspiratory port and at the patient-end of the expiratory part of the circuit. The gas was exhausted to the open air from the exhaust outlet on the console, and fresh air was introduced into the system. Residual formaldehyde was neutralized by circulating ammonia generated from a 1 in 3 dilution of 0.88 ammonia and exhausted. A ventilating cycle was then operated for one hour. Formaldehyde was circulated by running the ventilator at a tidal volume of 1 liter and a frequency of 20 ‘breaths’ per minute.			
Chemical concentration:	20 mL of 18 % formaldehyde (w/v) solution were evaporated in the console. The formaldehyde concentrations attained in the empty cabinet were between 0.3 and 0.9mg/L. The higher early peak levels fell sharply and, after 20 minutes, formaldehyde concentrations at all points remained around 0.4 mg/L. The formaldehyde levels obtained by evaporating undiluted solution and assaying from two sites within the ventilator circuit as well as at the cabinet sites were between 0.5 and 1.7 mg/L. Ventilator concentrations remained below 1 mg/L after 20 minutes and in the cabinet following early plot levels after 40 minutes.

HERO ID:	1317514			
Conditions of Use:	Use of fabric, textile and leather products			
EXTRACTION				
Parameter	Data			
Process description:	Formaldehyde is a major component in resins used to treat cotton fabric for shrink-resistant and crease characteristics. Treated fabrics usually contain some residual formaldehyde and off gassing may occur during subsequent processing. Fabric treatment systems may be divided generally into precure and postcure systems.<1 2) In postcure systems the final polymerization does not take place until the garment is manufactured. In precure systems, the final polymerization of the resin takes place in the finishing plant, and there is little residual formaldehyde. Cotton fabrics used in the garment sewing plant were precured.

EXTRACTION

Parameter	Data
Production, import, or use volume:	50,000 metric tons of UF, PF, and MF resins per year globally
Process description:	Fundamentally, spray drying involves the atomization of a liquid resin into a heated air stream. The spray dryer must be designed to minimize resin advancement (the increase of molecular weight) during the drying process. The four major components of a spray dryer are the drying air supply, the liquid resin atomizer; the drying chamber; and the product recovery system. Figure 1 shows a schematic flow diagram for a spray dryer and the components are briefly discussed. Drying Air SupplyThis component of the spray dryer involves a filter for the inlet air and an air heater. The heating of the air is generally accomplished via a gas burning. The heated air is mixed with the atomized resin and then passed through the drying chamber. The product and air are separated via a cyclone; the product is collected. Resin AtomizationResin atomization involves the conversion of the liquid resin into separated liquid droplets. The energy for this process can be imparted to the liquid stream by a variety of methods. In practice, there are three methods that have been employed for this process. The first, and most widely used, method to produce the resin droplets for drying is centrifugal force. This involves impinging the resin flow on a rotating disk. The disc can contain vanes, or other devices, to channel the flow to the edge of the disk. The revolution of these disks can be many thousands of revolutions per minutes with edge velocities of the disk reaching hundreds of meters per seconds. In general, rotary atomization has the advantage that resin feed pressure is lower than other atomization methods. In addition, this method provides more homogeneous products. A second method to achieve resin atomization is the use of a spray nozzle. This method involves pumping the resin through a rotating nozzle. The sudden pressuredrop on exiting the nozzle forces the liquid into many droplets. This method involves higher feed pressures than the rotary method described and provides a coarser and less homogeneous product. Also, nozzle plugging can be a problem when using this method of atomization. The final method for resin atomization is a kinetic process in which the liquid resin stream and the drying air are impinging on one another in a nozzle. The mixing can occur inside the nozzle (internal mixing) or outside the nozzle (external mixing). Variation of the fluid flows to the nozzle can modify the product size and shape. These atomizers provide more homogeneous products than the spray nozzle method, but suffer from nozzle blockage problems and relative high feed pressure for the liquid resin. As mentioned above, the rotary, or centrifugal, methods are generally used for resin powdered resin production. Drying ChamberThis is the largest component of the spray dryer. The size of the drying chamber will determine the residence time for the resin droplet and the ultimate capacity of the spray dryer. The drying of the resin droplet in the chamber is a two-step process. The first stage of the drying process occurs as the resin droplet leaves the atomizer and contacts the drying air: As evaporation occurs, a skin is formed on the surface of the droplet. At this point in the process, the surface of the droplet is saturated with moisture and the evaporation occurs at a constant rate. The temperature of the droplet at this stage in the process is essentially constant due to evaporative cooling. The second stage of the drying process occurs when the moisture level of the droplet is no longer sufficient to maintain a saturated surface. At this point, the remaining moisture in the droplet diffuses to the surface at a rate dependent on the thickness and porosity of the particle shell. This is also the point of the process where particle heating occurs. There is insufficient moisture for evaporative cooling to maintain a constant temperature and particle heating occurs. At this point, the dried droplet is removed from the drying air. Product RecoveryThe final step in the spray drying of resins is recovery of the product. As the flow exits the drying chamber, it consists of a mixture of the dried resin particles and moist air. The separation of the dried particles should be accomplished as soon as possible to minimize the amount of moisture that is transferred back into the dried particles. This separation is accomplished via cyclones, bag filters, or electrostatic precipitators.
Chemical concentration:	Typical liquid phenol formaldehyde (PF) resins for OSB contain approximately 50 percent water. Powdered resins, however generally contain greater than 95 percent resin solids.

EXTRACTION				
Parameter	Data			
Process description:	The laminate was built up of several layers of Impregnated paper sheets. The core consisted of papers Impregnated with phenol-formaldehyde resins, with resol resins based on phenol and formaldehyde the most common. The outer paper layer was Impregnated With melamine- formaldehyde resins (M-F-R). In varnishing machines, paper from rolls passed through a resin bath, which was filled from a closed system. The Impregnated paper then moved through a drying zone and was subsequently cut into sheets of appropriate size. The possible exposure of the workers to P-F-R at this stage occurred during cleaning of the machines or if the paper roll was accidentally broken. The next part of the process was stacking the Impregnated sheets of paper to achieve the desired laminate thickness. This was done manually by several workers and their hands were continuously exposed to uncured P-F-R. Following this step, curing took place in a press at a certain temperature, pressure, and time. Finally, the post-lamination processing of the product involved sawing, cutting and inspection steps, which were associated with skin exposure to dust from the laminate.			
Comments:	This data source pertains to the industrial use of resins based on phenol and formaldehyde (P-F-R) and melamine- formaldehyde resins (M-F-R) for the manufacture of decorative equipment by the impregnation of paper sheets with these resins.

EXTRACTION	
Parameter	Data
Process description:	Resin pellets produced at an Exxon facility in Baton Rouge, Louisiana, are usually shipped to the Pottsville plant by rail. Color concentrate and pellets made of recycled plastics arrive by truck. Recycled materials have been used in the plant for about a year and a half. The bulk handlers deliver the resin pellets by forklift to each of the ten blown film machines. There are two electric and ten propane forklifts in the polyethylene department. Pellets are gravity-fed into most machines, except for those on the upper level to which pellets are airpumped. Once in the machine, a combination of heat and pressure is used to melt the pellets. The machine is heated to 350oF and heat from friction raises the temperature of the molten resin to about 410oF. The molten material is then extruded through a die which has a chilled air ring. As this occurs, the material takes the shape of a bubble. This is a continuous sheet of polyethylene which ranges from 20-40 feet high depending on the machine set-up. On the five older machines (P-Line), the bubble air cools. The five new machines (500 Line) have a cooling stack inside the bubble. At the top of the polyethylene sheet is a series of rollers which collapse the bubble. The polyethylene then passes through another series of rollers where it receives an electrostatic charge which roughens the surface to allow it to accept printing ink applied by the customer. The air gap for this charge is 1/16 of an inch. The polyethylene tube is then slit to make two polyethylene sheets, which are then wound on a cardboard core. Any excess from the trimming process is returned to the extrusion area to be re-used. The machines located on the upper level operate in the same manner except that the melting and extrusion occur on the upper level and the slitting and winding occur on the lower level.

HERO ID:	1317290			
Conditions of Use:	Paper Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The Formica Corporation manufactures laminates by bonding several layers of resin-impregnated paper under pressure. Most of the resin used by the company is produced on site in their resin plant, located in a separate building adjacent to their main manufacturing plant, by combining formaldehyde, phenol, melamine, and various catalysts, inhibitors, carriers, and minor reactants. These resins are piped to the filler treating area -of the manufacturing plant, where they -are used to impregnate kraft paper either by spray or immersion. The impregnated paper is cut into four-by-eight foot sections to form filler sheets.Large pallets of filler sheets are taken successively to the filler sorting area, the collating area, and the press build-up area. Depending on the type of laminant being prepared, workers count out varying numbers of these filler sheets, pile them on a second pallet, add a cover sheet printed in the graining room with some pattern, possibly add a layer of material to give a special effect~ then add a separator sheet and repeat the process for successive layers. When a load of material is assembled in this manner, it is placed in a press where the sheets of each layer are bonded to one another to produce the laminate, with the separator sheets creating non-bonding barrier between laminates.

Parameter	Data
Process description:	At the time of the site visit, the company was producing gray iron from one furnace while the other furnace was being repaired.The furnaces were totally relined with a silica refractory each year. Metal scrap yards were located both inside and outside the facility.The metal pouring operation was performed on the day shift in two open areas inside the facility using stationary molds (large mold and small mold pouring). The metal was manually poured using the ladle fly-wheel. Overhead crane systems were used to position the ladles for pouring in both the small and large mold pouring areas. The molds were allowed to cool in the location where they were poured. A mold provides the cavity into which the metal is poured to produce a casting; a core is used to define the internal hollows desired in the casting. There were two coremaking areas: the smallcore room and the large coremaking area. Cores were made by hand and by machine. In the small core room, oil-based cores were baked in a gas-fired oven. In the large coremaking area, cores and molds were made of a phenolic-formaldehyde binder mixed with silica sand in an automatic mixer. A polymeric methylene phenylene diisocyanate (MDI) was used as the binder catalyst. The no-bake binders used were PEPSET I®, PEPSET II®, and PEPSET III®. Crane hoists were used for lifting small molds. A "blue dip primer" containing isopropanol, magnesium silicate, titanium oxide, and xylenes was utilized to seal the cores and molds after forming. The molds and cores were set afire to burn off the residual isopropanol in the primer to form a smooth surface. Compressed air was used to remove excess sand in the coremaking and molding departments.The metal castings were shaken out of the molds while still hot (referred to as "shakeout") on second and third shifts. A large shaker table was moved into the center of the large pouring area.Castings were lifted to the top of the shaker table using the overhead cranes and shaken out. For certain castings, compressed air was used to remove excess sand from internal cavities.Sledge hammers were also used to manually remove sand from the castings. A sand reclamation system with a side draft exhaust hood was used. Two Bobcat® front-end loaders were used to load the sand reclamation system and shake out some of the castings. The castings were loaded unto flat bed trucks, using cranes and chain hoists, and transported to another facility owned by the company for cleaning. Brooms were used to clean up excess dry sand throughout the facility.
Throughput:	the plant used two coreless electric channel furnaces which operated at 1500 kilowatts with a melt rate of 60 tons per day.

Parameter	Data			
Process description:	Bags of resin-coated sand (phenol-formaldehyde base with hexamethylenetetramine) are loaded into a sand hopper which feeds sand into the machine. The unit turns upside down and is heated to 450°F, creating a hard shell. Loose sand is shaken into the hopper. The complete cycle takes about five to seven minutes. The machine opens, and the core sis checked for flaws, and a water-based graphite core wash is applied . The core wash generates steam when applied to the hot cores. The green sand operation consists of an automated filling station, a conveyor system on which the molds are assembled, a conveyor pouring line, and a conveyor cooling line that leads to shake-out. The Pepset process uses an organic binding system containing an alkyd polyester, Stoddard solvent, polycyclodiene, 1,2,4-trimethylbenzene, dimethylethanolamine, 4,4'- diphenylmethane diisocyanate (MDI), polymethane polyphenyl isocyanate, xylene, a manganese compound, and a zinc compound. A heptane, talc, and mica-based coating is used. The resin is automatically added to the sand in the hopper. Recycled sand is used in this process. A three-part chemical system is used to produce the cores. Part I consists of a phenolformaldehyde based resin. Part II contains MDI, petroleum naphtha, and trimethylbenzene; and Part III is a drying agent which contains trimethylbenzene, xylene, and cumene. Recycled sand is used in this process. Pre-heated resin-coated sand is applied at the beginning of the conveyor system followed by a white Zircon™ wash. The box is turned over and goes through an infrared (IR) heater. Pepset cores into the bottom of the box and then add the top and close. Excess sand is removed using compressed air. Molds are lined up for the pouring.

EXTRACTION				
Parameter	Data			
Process description:	From the storage area, the material is moved to the staging area where it is pulled out of its protective bag and allowed to sit for at least a half-day before cutting. In the cutting department, the fabric is taken to either automatic spreading machines or to tables on which the fabric is hand-laid to match stripes. Occasionally, solvent-based adhesives are used to glue the pattern pieces in place. A band saw or straight knife is used to cut fabric and a rotary saw is sometimes used to cut elastic pieces. The cut pieces go to the bundling area where they are sorted into buckets (20 to 50 pieces depending on the garment to be made). Tote carts are used to transport the buckets to the sewing area. The sewing department utilizes a variety of machines, including three-thread, single-needle, multi-needle, flat-bed hemmer, pocket setter, tacker, labels, button-holer, snap, and needle-nose. The machines used vary, depending on the garment being produced. To reduce the size of needle marks in the fabric, a solution of silicone lubricant, fabric softener, and water is used on the material. The completed garments are taken to the finishing department, where they are inspected for things such as stitching, loose threads, matching stripes, spots, and stains. There are two spotting stations, used to remove stains from the garments, located adjacent to the sewing department. These spotting stations are used as needed. A heat press is used occasionally for fusible pella fabric. After inspection, the garments are folded and packed to ship to the customer. (page 10-11 of 32)

Life cycle description:	Formaldehyde has four major applications: as an intermediate in the manufacture of melamine, polyacetal, and phenolic resins; as an intermediate in the production of industrial chemicals; as a bactericide or fungicide; and as a component in the manufacture of end-use consumer products. Phenol-formaldehyde resins are used in the production of plywood, particleboard, foam insulation, and a wide variety of molded or extruded plastic items. Formaldehyde is also used as a preservative, a hardening and reducing agent, a corrosion inhibitor, a sterilizing agent, and in embalming fluids. Indoor sources include upholstery, permanent press fabrics, carpets, pesticide formulations, urea-formaldehyde foam insulation, and cardboard and paper products. Outdoor sources include emissions from fuel combustion (motor vehicles), industrial fuel combustion (power generators), oil refining processes, and other uses (copper plating, incinerators, etc.). The largest portion of outdoor ambient formaldehyde results from photochemical oxidation of a number of reactive organic gases in the atmosphere

EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Brazil is the largest wood charcoal producer at 5 million tons (2009)			
Life cycle description:	Reactant: charcoal production			
Process description:	The charcoal production process consists of burning wood, usually Eucalyptus or Pinus varieties that are grown on plantations, in an oxygen-poor environment in brick kilns. The rudimentary brick kilns have several small orifices and lateral exhaust chimneys (stacks). The kilns are usually devoid of any system for controlling or eliminating the emission of smoke into the atmosphere. Briefly, the production process consists of four primary activities: (1) tree cutting, (2) filling the kilns, (3) combustion (carbonization) of wood in the kilns, and (4) removal of the charcoal. The wood combustion process takes up to 7 days in these types of kilns, and it varies according to the size of the kiln and the density and freshness of the wood. The carbonization process is completely dependent on the knowledge of a worker (kiln burner), who examines the color and the amount of smoke to assess the stage of combustion. The emission of smoke is more intense during the beginning of the burning process, and a blue and transparent smoke indicates the conclusion of the carbonization process. At that time point, the oxygen content in the kiln is gradually reduced by covering the kiln orifices with pieces of brick and clay as the pyrolysis progresses. When the carbonization is complete, the kiln workers manually remove the charcoal. Manually loading wood and unloading charcoal are still the standard procedure in most parts of the country.

Study Citation: Ceballos, D., Boradwater, K. (2015). Evaluation of occupational exposures at a drycleaning shop using SolvonK4.				
HERO ID: 8684521				
Conditions of Use: Dry cleaning solvent				
EXTRACTION				
Parameter	Data			
Process description:	Fabrics, including clothes, drapes, and other textiles, were received from customers, labeled, and sorted for cleaning. Prior to dry-cleaning, some stained fabrics were pre-cleaned or spot cleaned. The shop used several spot-cleaning agents including a custom mixture of 40% SolvonK4, 40% PrenettK4™, and water or undiluted Greased Lightning® Super Strength cleaning product. The dry-cleaning machine cleaned fabrics by saturating them with SolvonK4 in enclosed drums. The cleaning cycle was 70 to 80 minutes. Cleaning additives (e.g., ClipK4™ detergent and PrenettK4 spotting agent) were automatically injected into the solvent flow line or into the drum of the dry-cleaning machine. At the end of the cleaning cycle, the solvent was automatically removed by draining and then heating and tumbling the cleaned fabrics under vacuum to remove any that remained. Employees manually spot-cleaned fabrics that were still stained or soiled after dry-cleaning with the same products used in precleaning. Employees pressed the cleaned fabrics and ironed as needed, then hung them on hangers covered with plastic wrapping while awaiting customer pick-up or delivery. (5/22)			
Throughput:	The shop dry-cleaned 20–40 loads per week. (7/22)			
Chemical concentration:	Bulk analysis of SolvonK4 revealed that this solvent contained more than 99% butylal, 0.05% butanol, and less than 0.00045% formaldehyde. (9/22)			
EVALUATION

Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	High	Uncertainty is addressed in sampling/analytical methodology in the study. Variability addressed by sampling multiple locations and different job operations.
Overall Quality Determination		Uninformative		

Study Citation:	Ceballos, D., Roberts, J., Whittaker, S., Lee, E. G., Gong, W. (2015). Evaluation of occupational exposures at drycleaning shops using SolvonK4 and DF 2000.			
HERO ID:	8684520			
Conditions of Use:	Laundry and dishwashing products			
EXTRACTION				
Parameter	Data			
Process description:	In the shops that we evaluated, the drycleaning machines had enclosed drums where the fabrics being cleaned were saturated with the drycleaning chemical. In all the alternative solvent drycleaning machines we observed in this evaluation, any cleaning additives (e.g., detergent, stain repellant) were injected into the solvent flow line or into the drum of the drycleaning machine (in contrast to an older method that involved predissolving the detergent in the solvent). When the cleaning cycle was complete, the solvent was drained, and the cleaned fabrics were placed under vacuum, heated, and tumbled to remove any remaining solvent. Employees could manually spot-clean fabrics that were still stained or soiled after drycleaning, using the same products used in precleaning. The cleaned fabrics were pressed (Figure 1) and ironed as needed, then hung on hangers and covered with plastic wrapping awaiting customer pick-up.Modern drycleaning machines prevent the release of solvent vapors to ambient air by recycling the solvent in a closed loop system and automatically evacuating the air in the cleaning chamber before the machine is opened. The heated solvent vapors generated during the drying cycle pass through a refrigerated condenser [LHWMP 2014a]. The condenser cools the air and condenses the solvent vapor to be recovered. Recovered solvent is then pumped into a vacuum still. This distillation process prevents impurities from building up in the solvent. Steam coils in the still heat the solvent to boiling. The solvent vapors flow through a condenser to removewater. This process also generates a concentrated waste material called “still bottoms” that contains residual solvent in addition to nonvolatile components, such as detergent, sizing, waxes, oils, and greases. After the drycleaning machine has cooled (usually overnight), the still bottoms are manually transferred to a waste container (Figure 2) with a specially designed rake, usually by the shop owner. Depending on the volume of drycleaning processed in a shop, the still bottoms are removed every 1–2 weeks.(pg. 8)			
Chemical concentration:	The drycleaning SystemK4 developed by Kreussler GmbH uses SolvonK4, a chemical that contains primarily butylal (> 99%), with small amounts of n-butanol (< 0.5%) and formaldehyde (< 0.05%). (pg. 7) NIOSH analyzed bulk sample of SystemK4 and measured 0.007% (pg. 12)			
Comments:	In addition, additional process information is given on drycleaners but extracted only for site that used formaldehyde containing product.

EXTRACTION	
Parameter	Data
Process description:	Fabrics, including clothes, drapes, and other textiles, are received from customers, labeled, and sorted for cleaning. Prior to dry cleaning, stained fabrics may be pre-cleaned or “pre-spotted.” Many different spot cleaning agents are used in the shops. These products are formulated according to the types of stains to be removed (i.e., hydrophilic or hydrophobic stains). Modern dry cleaning machines use enclosed drums where the fabrics being cleaned are saturated with the dry cleaning solvent. Cleaning additives (e.g., detergent, sizing or fabric finishes, and stain repellent) are injected into the solvent flow line or into the drum of the machine (in contrast to an older method that involved predissolving the detergent in the solvent). When the cleaning cycle is complete, the solvent is drained, and the cleaned fabrics are placed under vacuum, heated, and tumbled to remove any remaining solvent. In our evaluations the duration of the dry cleaning cycle for SolvonK4 and DF- 2000 machines was 70–80 min. Workers can manually spot-clean fabrics that are still stained or soiled after dry cleaning by using the same products used in precleaning. The cleaned fabrics are pressed (Figure 1) and ironed as needed, then hung on hangers and covered with plastic wrapping awaiting customer pick-up. Modern dry cleaning machines like the ones we evaluated minimize the release of solvent vapors to ambient air by recycling the solvent in a closed loop system and evacuating the air in the cleaning chamber before the machine is opened. The heated solvent vapors generated during the drying cycle pass through a refrigerated condenser. The condenser cools the air and condenses the solvent vapor to be recovered. Recovered solvent is then pumped into a vacuum still. This distillation process prevents impurities from building up in the solvent. Steam coils in the still heat the solvent to boiling. The solvent vapors flow through a condenser to remove water. This distillation process generates a concentrated waste material called “still bottoms” that contains residual solvent in addition to nonvolatile components such as detergent, sizing, waxes, oils, and greases. After the machine has cooled (usually overnight), the still bottoms are manually transferred to a waste container (Figure 2) with a specially designed rake, usually by the shop owner. Depending on the volume of dry cleaning processed in a shop, the still bottoms are removed every 1–2 weeks.

EXTRACTION			
Parameter	Data		
Production, import, or use volume:	less than 500 million lbs (less than 0.5%) were POM, global annual POM production exceeds 1,000 kiltons (pg. 3)		
Life cycle description:	POM copolymer (from formaldehyde-derived compounds) products are used in automobiles, medical devices, specialty consumer products, and a variety of other high-value applications (pg. 2)		
Process description:	Production processes include oxidation of methanol to formaldehyde; reaction of formaldehyde to form trioxane, dioxolane, and paraformaldehyde; polymerization of the formaldehyde-derived chemicals into POM; and formation of the polymers into pellets or flakes.Die face and underwater cutting are generally enclosed processes used for highest volume manufacturing. Lower volume production may also use strand cut systems, which force the polymer out of a die to create strands that are quickly pulled through a water bath and chopped to pellets. Most of this low-volume strand cutting occurs outside of enclosures...as the polymer is extruded, the strands are directed through water baths, which both solidify the polymer and absorb any formaldehyde emissions. Most POM polymer as pellets to customers who process those pellets directly into products or parts. A small portion is shipped in a flake form that is provided to processors who may add their own colorants or additives in an extrusion process(pdf pg. 5)		
Chemical concentration:	Residual formaldehyde in specialty is low, at approximately 100 mg/kg, or 0.01% by weight. Celanese specialty polymers contain less than 1 ug/cm2 (pdf pg. 12)

EXTRACTION

Parameter	Data
Process description:	Processes involving formaldehyde include the following: (A) Name - Methacrylic acid/methyl methacrylate (MMA-) process, Raw materials - ethylene + CO/H ₂ + formaldehyde, Product - methyl methacrylate, Originality - (1) hydrocarbonylation of ethylene to propionaldehyde, (2) condensation with formaldehyde to methacrolein, (3) oxidation to methacrylic acid, (4) esterification with methanol; (B) Name – Citral process, Raw materials – isobutene, formaldehyde, Products – citral, intermediate for ionone, carotins, vitamine A, Originality - cheap, easily available starting materials oxidation with O ₂ . In the BASF methacrylic acid/methyl methacrylate (MMA-) process, ethylene, syngas, formaldehyde and methanol are used as starting materials for the production of MMA. In the first step of this process, ethylene is hydroformylated to propionaldehyde in the presence of a Rh/Co-triphenylphosphine at 130 degC approximately and 15 bar. In a following Mannich-condensation, propionaldehyde is condensed with formaldehyde in an adiabatic reactor to form methacrolein in high yields above 90%. This reaction is carried out at 160-210 degC and 45-50 bars in the presence of dimethylamine in acetic acid. In the third step, methacrolein is oxidized with oxygen in the gas phase over a heterogeneous catalyst in a fixed bed reactor. The methacrylic acid is isolated and sold or is converted to MMA with very high yield in a classical acid catalyzed esterification with methanol. The BASF process has the favorable advantage of cheap easily accessible raw materials; however, there is a need for integrated production site to make the process more profitable. The BASF process for manufacturing citral starting from isobutene and formaldehyde is a noteworthy and outstanding example of the use of molecular oxygen in the synthesis of fine and intermediate chemicals. The BASF route starts from comparatively cheap isobutene and formaldehyde. In this condensation reaction, 3-methyl butene-3-01 (isoprenol) is formed. A part of this alcohol is isomerized in the process. The notable central step in this new process is the regioselective oxidation of this alcohol to the corresponding aldehyde over a special supported silver catalyst in the gas phase. This is the key precursor for citral manufacture developed by BASF researchers. In a continuous flow reactor at 500°C and a residence time of about 0.001 s, isoprenol is transformed in the presence of excess of oxygen to the temperature sensitive isoprenal with 95% yield. In order to keep the residence time short and to avoid hot spots, the reaction has to be carried out in a short fixed bed reactor. In a following Cope-rearrangement citral is formed from isoprenol and isoprenal. This example demonstrates nicely that even temperature-sensitive fine chemicals such as isoprenal can be produced in a commercial unit operating in the gas phase with molecular oxygen as oxidant.

HERO ID:	8016652		
Conditions of Use:	Other- Byproduct of Biocide in MWF		
EXTRACTION			
Parameter	Data		
Process description:	The Robinson Run mine uses the continuous and longwall methods to mine coal from the 7.5-16 foot thick Pittsburgh coal seam. Continuous miners are used to develop entryways for the longwall panel. The longwall panel is a 1000 foot wide passageway whose roof is supported by 98 hydraulic shields. A track mounted, chain driven shearer with a rotating drum takes a 2-foot deep cut from the seam of coal as it moves up and down the 1000-foot face. The shearer is equipped with water sprays that are used for dust suppression. The cut coal falls onto a panline and is transported to the headgate (fresh air entry point to the longwall panel). At the headgate, the coal passes though a stage loader and onto abeltline where it is transported out of the mine along a fresh air entryway. The longwall panel is ventilated with approximately 60,000 cubic feet per minute of fresh air that passes from headgate to tailgate. The longwall sections are associated with high relative humidity (i.e., >70 percent) during the summer months as a result of intake air being cooled to mine temperature (about 70-74 degrees Fahrenheit dry bulb during the summer) and as a result of water sprays being applied as a dust suppressant at the shearer and along the beltline.		
Throughput:	Solcenic HL concentrate was delivered, at 3-5 week intervals, in 5,000-gallon truckloads to an 8,000- gallon tank that is located in a surface building. The dilution ratio is 24 parts water to one part Solcenic HL concentrate. The 4-percent emulsion is piped from the surface by gravity feed some 3.5 miles into the mine to replenish losses in a closed loop system.Based on a estimated annual delivery of 65,000 gallons of concentrate (one truckload every four weeks) and a dilution rate of twenty four parts water to one part concentrate, approximately 1,500,000 gallons of the diluted emulsion were piped into thehydraulic system in the preceding year		
Chemical concentration:	Solcenic HL is a hydraulic fluid that is mixed into a4 percent emulsion with water during use. The fluid does not contain formaldehyde but contains triazine compound (acts as a biocide by decomposing into formaldehyde).

HERO ID:	6028034			
Conditions of Use:	manufacture			
EXTRACTION				
Parameter	Data			
Process description:	The reaction of formaldehyde with cellulosic fabrics depends a number of factors, including (1) the reactant composition, (2) the nature and amount of the catalyst, (3) the time and temperature of cure, (4) impurities in the formaldehyde reactant, (5) the condition of the fabric, and (6) the additives to the impregnating bath. The amount of formaldehyde released from the treated fabric will depend on all of these factors plus the effect of rate of hydrolysis, concentration of reactant, free formaldehyde in the impregnating bath, afterwashing of the treated fabric (if carried out) and any aftertreatment of the fabric such as treatment with a compound that will react with formaldehyde.			
Chemical concentration:	no available information

HERO ID:	6201928			
Conditions of Use:	Sterilization			
EXTRACTION				
Parameter	Data			
Process description:	One type of sterilizer that has gained wide popularity is the chemical vapor sterilizer or Chemiclave. It has the advantage of limiting the rusting, dulling, or corroding of metal instruments, which is a big concern in dental offices. The chemical vapor sterilizer uses heat, pressure, and a chemical vapor to achieve sterilization. The chemical solution that produces this vapor is composed of ethyl alcohol, isopropyl alcohol, tertiarybutyl alcohol, methyl ethyl ketone, acetone, and formaldehyde.			
Throughput:	The manufacturer indicates that the Chemiclave vaporizes approximately 15 ml of the chemical solution during a single sterilizing cycle. The first sterilizer averaged 7.7 cycles per day, while the second sterilizer averaged 4.5 cycles per day			
Chemical concentration:	When the condensate of the chemical vapor was analyzed, it was found to contain 2% formaldehyde

HERO ID:	8140526			
Conditions of Use:	Finishing agents in textiles, apparel, and leather manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The company receives pre-cured, finished fabric from a textile finishing plant. The shirt fabric is treated with formaldehyde-based resins at the finishing plant which give the fabric crease-resistant characteristics, and the resin treated fabric is cured before it is received by the plant. The first step in the process is the cutting of shirt parts from the fabric. Many layers of fabric are spread out, one on top of another, on a long table. All of the layers are cut with handheld saws or with dies. After cutting, the shirt parts are assembled. Most of the various assembly require sewing machines. Some operations make use of heat to form of fuse together parts. The finished shirts are moved to the apparel press operation where conventional hand irons are used to press the shirts. (5/16)			
Chemical concentration:	An 80/20 polyester/cotton blend had 93 ppm formaldehyde. Collar fusing material had 1440 ppm formaldehyde by weight. (15/16)

Life cycle description:	Fibrous material manufactured is used for thermal and acoustical insulation				
Process description:	Delivery and unloading of raw material (sand, limestone, soda ash feldspar, and borax); transport to storage silos. Mix to form the raw batch that is transported using a screw auger to the furnace for melting. In the furnace the batch is converted to a homogenous mass of molten glass. the molten glass leave the furnace after passing under a skimmer and through the throat, which is below the level of the molten glass. Connected to the throat, is the forehearth which acts as a channel to move the glass into the fiberizer. The glass fiber is produced when the molten glass passes through the fiberizer. Directly under the fiberizers are cooling fins and a spray of water . the water spray is followed by a solution of phenolic resin binder (phenol, formaldehyde) urea, ammonium sulfate, petroleum emulsion, anhydrous ammonia and carbon black. The binder solution is sprayed on the fibers as they are collected on a conveyor belt. The binder solution coasts the fibers for lubrication and protection of the fibers. It also provides for reinforcement and better bonding of the fibers, and gives them a specific handling characteristic. The mat of fibers is then wound onto a rotating cylinder. The rolled mat of fibers may then be removed for storage and drying. For some specific products, additional drying may be necessary. If this is the case the mat is not collected on the rotating cylinder but is passed through a drying oven before being cut. Depending how they are to be used, the mat is either stored and shipped form the plant or are moved to the molding department. The molding department has 3 production lines where the mats are placed in molds and then into a heated press to form the desired item. The items placed on the sterling line are sprayed with a black fire resistant coating.

Study Citation:	CPChem, (2002). Initial submission: Ltr fr CPChem to USEPA reporting residual production of formaldehyde in a polystyrene production unit, dated 102402.			
HERO ID:	6574134			
Conditions of Use:	Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The article is related to residual production of formaldehyde in a polystyrene production unit. Production of formaldehyde from oxidative decomposition of polystyrene at temperatures of about 250 degrees C has been demonstrated in the literature. However, the facility in this article reports formaldehyde production from decomposition of polystyrene in polystyrene production process when the reactor temperature is maintained between 135 degrees C and 155 degrees C, which are far below the temperature expected for.			
Chemical concentration:	During recovery and condensation of un-reacted styrene vapors, a white semisolid residue is deposited in the condenser tubes. A sample of this white material indicated that the material was approximately 30% paraformaldehyde, 68% water, 0.4% styrene, and the remainder being possibly polystyrene. Paraformaldehyde is formed from polymerization of formaldehyde as a result of cooling in the condenser tubes.

Study Citation:	CPSC, (1982). Investigation of exposure to formaldehyde from preserved biological specimens.			
HERO ID:	6574135			
Conditions of Use:	Laboratory Chemical			
EXTRACTION				
Parameter	Data			
Process description:	Formaldehyde is the fixative of choice for animal specimens. Animal specimens used for teaching purposes are either pickled by immersion in the formaldehyde solution or embalmed by injection of the formaldehyde solution directly into the body cavity or circulatory system. An estimated 75 percent of all specimens are embalmed. After being “fixed”, specimens traditionally packed in a 3.7% formaldehyde solution, and shipped to teaching laboratories in pails or barrels. The preservation process retards spoilage, permitting ample time for transport of the specimens and for students to work on specimens for the weeks or months necessary to the learning process			
Chemical concentration:	10% formalin (3.7 percent formaldehyde in water) traditionally has been used as a biological tissue fixative. The fixative solution may contain, in addition to formaldehyde and other aldehydes, water, phenol, and alcohol.

Study Citation:	CPSC, (1982). Preliminary economic report on the use of formaldehyde in school laboratories.				
HERO ID:	6574136				
Conditions of Use:	Laboratory Chemical				
EXTRACTION					
Parameter	Data				
Process description:	Formaldehyde is manufactured from methanol (methyl alcohol)				
Chemical concentration:	Because gaseous formaldehyde is unstable and difficult to handle, it is usually sold in solution with water. Typically, such a solution contains 35-40% formaldehyde by weight, and is referred to as formalin. Methanol (1-15% by weight) is almost always present in formalin and acts to stabilize the dissolved formaldehyde, which has a tendency to polymerize. Other concentrations, both in and various other alcohols, are available.

Parameter	Data		
Process description:	The retanning process is the main application of formaldehyde in the tanning industry since formaldehyde participates in two groups of synthetic organic tanning agents: syntans and resins. Resins can be hydrolyzed with the result that formaldehyde is released. Thus formaldehyde in leather can be free or from hydrolysis of resins. In the tanning industry, formaldehyde has a wide and variety of applications. Traditionally formaldehyde was used as tanning agent because of its ability to crosslink collagen. However, today there has been mostly replaced by glutaraldehyde and other aldehyde derivatives. In the production of wet-white, formaldehyde still has some application to stabilize the hide before splitting orshaving: "as a preservative, in dilutedversions of certain chemicals in the wet-end andfinishing operations; as fixing agent in protein finishessuch as casein and in the dyeing process of someunfinished leather articles like suede or nubuck and inthe ironing of wool in furriery." "the main causes of itspresence in leather at present are: impurity in syntansand resins (very frequent presence in products of Asianorigin); residue of the fixing operation of proteinfinishes such as casein (rare presence); residue of theironing of wool in furriery (frequent presence) andresidue as preservative in chemicals in the wet-endoperations (frequent presence)."		
Chemical concentration:	[mg formaldehyde/kg article] Table 4 ranges from 27.4-415(HPLC); Table 5 4.7-200(colorimetry); Table 6 13.6-151 (different agitation)

EXTRACTION

Parameter	Data
Process description:	The Woodbridge Brodhead plant produces flexible polyurethane foam cushions for automobile seats. The process involves commonpolyurethane foam chemistry, the core reaction of which is a diisocyanate reacted with a polyol/resin mixture to form a carbamate, commonly referred to as a polyurethane. The diisocyanate used at the plant is the monomeric form of a mixture of 2,4- and 2,6-isomers of TDI. TDI is delivered to the plant by either rail car or tank truck and is offloaded under positive pressure into one of five, 5000-gallon storage tanks.Woodbridge Brodhead operates two production lines: A-line and B-line, both of which are in nearly continuous operation. Each line consists of a chain of heated molds which continuously cyclethrough a series of stations. The stations are as follows: 1) wax application, 2) insert, 3) pourhead, 4) heating/curing oven, and 5) demold. A robot applies the wax to molds on the B-line. On the A-line wax is applied manually. The term “wax dispersion” is used to describe the liquid form in which wax is applied to the mold bowls. The liquid formulation is a wax dispersed in naphtha solvent. The waxdispersion is applied to the bowl of the mold using an air atomization spray gun. The organic solvent evaporates upon contact with the heated mold, leaving a wax residue. This residue prevents the foam cushion from adhering to the mold. In the insert area, components such as metal frames/wires and velcro patches are inserted into the bowl of the mold before it reaches the pourhead. The pourhead is the point where the TDI and polyol components come together and the mixture is dispensed by a robot into the bowl of an open mold. Each of the pourheads is fully automated. The molds close as they move away from the pourhead and into the heating/curing oven, which is maintained at a nominal temperature of 150 degrees Fahrenheit. A mold moves through the oven in four minutes as the foam should fully set. The lid of the mold opens as the mold moves from the oven to the demold area.At the demold work station, the foam cushions are loosened and removed from the molds, trimmed, sorted, inspected, and repaired. The finished foam cushion is then placed on a conveyor belt. Next, the mold is cleaned in preparation for the next cycle.
Comments:	Noted that the source of formaldehyde is within the plant, but actual sources could not be identified.

EVALUATION

Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	The study uses high quality data from frequently used source (NIOSH HHE)
Domain 2: Representativeness	Metric 2: Geographic Scope	High	US
	Metric 3: Applicability	Low	The data are for an occupational scenario but the source of formaldehyde exposure is unknown. "Thesource of the formaldehyde at the Brodhead plantis unknown at this time."(p. 30) Therefore data cannot be matched with a COU within the scope of the risk evaluation, however it may be suitable for commercial use of building materials
	Metric 4: Temporal Representativeness	Low	1999 - more than 20 years old.
	Metric 5: Sample Size	N/A	This report provided qualitative information
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	This report clearly documents its data sources (IH site visit)
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	N/A	This report is site-specific data so variability and uncertainty is not applicable

EXTRACTION				
Parameter	Data			
Process description:	Prior to electroplating, the surface of the workpiece is thoroughly cleaned with solvent. Acid solutions are used to remove layers of metal oxides, and alkaline solutions are used to remove oils and solids. A water rinse tank is used after the cleaning. During electroplating, an anode, cathode, and electrolytic solution are placed together. The application of a current causes a migration of the metal ions from the electrolyte solution to the cathode where they are deposited onto the base metal. Metal from the anode then dissolves into the solution to replace the metal ions as they are depleted from the electrolyte. (5/25)

EXTRACTION	
Parameter	Data
Process description:	The Shelbyville plant is one of three fibrous glass plants owned by Pittsburgh Plate Glass Industries and is the only facility manufacturing wool insulation. The other two plants are located inLexington, North Carolina and Shelby, North Carolina. Both of theseplants manufacture fibrous glass textiles (yarns and rovings).Fibrous glass is formed at Shelbyville by either centrifugalfforming or flame-jet forming. Flame jet forming is designated as "Superfine" by the company and centrifugal forming designated "Rotary". There are five superfine lines in this plant and one rotary line.Glass charges for both types of furnaces are mixed in a batchhouse. Boro-silicate glass is made and the raw materials includesand (50%), soda ash (14%), B203(12%), nepheline syanite (12%), fluorspar, rutile, and clay. Rutile is being phased out due to its high cost.Both hand and automatic mixing are used. The major raw materials(sand, etc.) are pneumatically conveyed from storage silos outside the building to the mixer. The minor ingredients are weighed and hand dumped into a mix station where a bucket elevator carries the materials to the mixer. After the raw materials are completely mixed they are either emptied into batch cans for the superfine furnaces or pneumatically conveyed to the rotary furnace.In the flame jet forming process, glass batch is fed into thefurnace where boro-silicate glass is formed at temperatures of approximately 2500°F. After the glass is formed, it is fed into a refractory container known as a forehearth where the glass is held at approximately 2250 F. The glass next flows through platinum bushings in the bottom of the forehearth to form primary fibers of rather large diameter. Upon leaving the forehearth the primary fibers are fed into high velocity gas flame blowers which further attenuate the fibers into desired diameters by a pulling action.As the attenuated fibers move away from the blowers, a phenol-formaldehyde binder is applied by a spraying process. The fibers, which are coated with the uncured binder, are collected on a conveyor, thus forming a continuous blanket.After the glass fiber blanket leaves the forming area, the bindermay be cured or left uncured. Blankets used as home insulation arecured in an oven at temperatures between 400 and 500°F. Blankets used to make molded pipe insulation are left uncured. Home insulation is either cut into bats or rolled onto a cardboard tube following curing. Uncured blankets are rolled and taken to the pipe insulation area for further processing.The only major difference between centrifugal forming and flamejet forming is the method used to form fibers. In the centrifugalfforming process, glass from the forehearth is fed into spinners where centrifugal force is used to force the glass through small holes in the periphery of the spinner thus forming fibers. Upon leaving the spinners, each glass fiber is met by a high velocity air stream which further attenuates the fibers. A phenol-formaldehyde binder is also added at this time. The centrifugal forming process at Shelbyville uses three spinners with a total of 90,000 cfm being drawn through the forming hood. The operations which follow forming are the same as previously mentioned for the superfine process.Molded pipe insulation is made from superfine mats coated withuncured phenol-formaldehyde binder. The mats are cut to length and rolled onto a steel mandrel and then clamped between two forming halves. The assembly is then cured in an oven at 500°F. Following curing, the mandrel is removed, the ends are trimmed, and the insulation cut into halves. Finally a vapor binder is applied to the outer surface and the material packed for shipment.Flexible fibrous glass air ducts are constructed from mats madein the rotary process. In this process, the glass mat is woundaround a steel wire cage and the ends glued together. A polyethylene covering is next slide over the duct. These ducts are next inspected and packaged for shipment. The glue used in this process uses acetone and n hexane as solvents.The final process to be discussed is the manufacture of "textrafinell insulation mats. This process is mainly one of "scrap recovery" although the resulting product is higher in cost than other insulation blankets.In the textrafine process, textile scraps are received from PPG's two North Carolina plants and scraps from this facility are shredded, dried, and baled. These bales are next fed into breakersand blenders similar to those used in textile mills. From the blender, the fibers enter a carding section where the fibers arecombed into parallel position to form a tenuous web. High velocityair is next used to blow a powdered phenolic resin onto the fibers.The fibers, impregnated with resin, are next collected on a conveyor to form a mat and cured in a curing oven. Following curing, the mats are cut and packed for shipment.

HERO ID:	4741999
Conditions of Use:	FA use in manufactured plywood.

EXTRACTION	
Parameter	Data
Process description:	2 mm-thick rotary cut veneers with the dimensions of 500 mm by 500 mm were obtained from beech, poplar, alder, and scots pine logs. A lab scale rotary type peeler with a max horizontal holding capacity of 800 mm, was used for manufacturing veneer. While the alder and poplar veneers were manufactured from freshly cut logs, beech and spruce logs were steamed for 12 h before veneer production. The main function of steam heating is to soften the veneer log temporarily, making it more plastic, pliable, more readily peeled, and improving the quality and quantity of the material recovered from the log. Therefore, beech and spruce logs were steamed to make easier the rotary cutting, whereas alder and poplar veneers were manufactured from freshly cut logs because alder and poplar logs can be peeled freshly. The horizontal opening between knife and nosebar was 85 % of the veneer thickness, and the vertical opening was 0.5 mm in rotary cutting process. The veneers were then dried to 6-8 % moisture content in a veneer dryer. After drying, veneer sheets were treated with some fire retardant chemicals. For this aim, 5 % aqueous solutions of zinc borate, boric acid, monoammonium phosphate (MAP) and ammonium sulfate were used. The veneers were subjected to re-drying process at 110 °C after they being immersed in the fire retardant solution for 20 min. Three-ply-plywood panels, 6 mm thick, were manufactured by using two types of urea formaldehyde resin with different free formaldehyde ratios. The formulations of adhesive mixtures used for plywood manufacturing are given in Table 2. Veneer sheets were conditioned to approximately 5-7 % moisture content in a climatization chamber before gluing. The glue mixture was applied at a rate of 160 g/m2 to the single surface of veneer by using a fourroller glue spreader. Hot press pressure was 12 kg/ cm2 for alder and beech and 8 kg/cm2 for scots pine and poplar panels, while hot pressing time and temperature were 6 min and 110 °C, respectively. Two replicate panels were manufactured for each test group.
Chemical concentration:	Formulations of Urea-formaldehyde glue mixtures are in Table 2: UF1 free formaldehyde max: 0.16%; UF2 free formaldehyde max: 0.20%

Conditions of Use:	Textile Finishing

EXTRACTION

Parameter	Data
Production, import, or use volume:	1.68 x 10 ⁹ m ² of leather made annually around the world (2001)
Life cycle description:	Fig 1 provides all possible technological operations from raw hide to finished product: raw hide → pre tanning (trimming, soaking, liming, unhairing, reliming, fleshing, deliming, bating, scudding, pickling) → pelt → tanning (chrome/vegetable-tanning, basification, piling) → Wet Blue leather → Post tanning operations (sammying, splitting, shaving, re-chroming, neutralization, re-tanning, fat-liquoring, dyeing, setting, drying) → Crust Leather → Finishing operations (conditioning, staking spraying/roller coating, toggling, trimming buffing, measuring, plating/polishing) → finished product.
Process description:	Manufacturing process for leather preparation can be divided into 3 basic sub-processes: preparatory stage/beam house stage, tanning stage and crusting stage. Surface coating may be an addition step into the leather process. Preparatory stage or the beam house operation stage is carried out when the hide/skin is prepared for tanning. This stage includes preservation, soaking, liming, unhairing, fleshing, splitting, reliming, deliming, bating, degreasing, bleaching, pickling and depickling. At the onset, the hides are trimmed and soaked not only to restore the lost moisture during curing but to get rid of salt and other solids. Subsequently, the hides are fleshed to remove excess tissue, muscles or fat adhering to the hide so that uniform thickness may be obtained. Dehairing is performed mostly by liming process using a series of drums containing lime liquors (calcium hydroxide) and sharpening agents, however thermal, oxidative, and chemical methods may also be applied. The softness and flexibility to the leather may be obtained by bating and deliming, which is performed by keeping the hides in a solution of ammonium salt dissolved in water along with proteolytic enzymes at 27-32C. Pickling is required as the next step to adjust the acidity with the use of a brine solution and sulphuric acid. Tanning converts the rawhide or skin into a stable material that dries out to a flexible form without putrefying and becomes suitable for a wide variety of end applications. In general, depending upon the end application of the leather, two tanning methods is used; vegetable tanning or chrome tanning. The process of vegetable tanning usually requires 3 weeks so that the dye penetrates to the hide. Further, the hides are dipped in sodium bicarbonate or sulphuric acid drums for bleaching and for the removal of tannins bound to the surface. Before set out to dry, lagnosulfate, corn sugar and oils may be added to the leather and then it undergoes further finishing steps. Chrome tanning is done by the reaction between the hide and trivalent chromium salt, most commonly basic chromium sulphate. At pH 3 the tanning materials are introduced and the pH is raised. The soaking, fleshing, liming/dehairing, deliming, bating, and pickling and the drying/finishing steps are essentially the same as in the case of vegetable tanning except that an additional processes of retanning, dyeing, and fat liquoring to produce usable leathers. Many a times oil is applied on the skin before leather drying to replace the natural oil lost during beam house and tanyard processes; this step is called fat liquoring. The leather is thereafter wrung, set out, dried, and finished. The pH of chrome tanned leather finish between 3.8 and 4.2. Chrome-tanned leather is more superior to vegetable tanned leather due to its softness, high thermal and water stability and less time consuming. Almost all leather made from the skin of sheep, lambs, goats, pigs is chrome tanned. Crusting takes place after the thinning, re-tanning and lubricating of the hide. Sometimes dye is also added in this process. During crusting, the chemicals added have to be fixed followed by drying and softening process. Crusting involves several steps like wetting back, sammying, splitting, shaving, re-chroming, neutralization, re-tanning, dyeing, fat liquoring, filling, stuffing, stripping, whitening, fixating, setting, drying, conditioning, milling, staking, and buffing. Finishing process consists of surface coating that include: oiling, brushing, padding, impregnation, buffing, spraying, roller coating, curtain coating, polishing, plating, embossing, ironing, combing (for hair-on), glazing and tumbling...”The use of formaldehyde is inevitable in the manufacture of various types of leathers due to its action as cross linker for casein top coats.”
Chemical concentration:	Mandatory residual substance limits in leather products: Germany - >1500 ppm; Austria - >1500 ppm; France - 200-400 ppm; Netherlands - 120 ppm

HERO ID:	5968910
Conditions of Use:	Urea formaldehyde resin for wood based panels

EXTRACTION

Parameter	Data

Production, import, or use volume:	UF resins are the most important type of the so-called aminoplastic resins. Currently, approximately 6 billion tons are produced per annum worldwide, based on a usual solids content of 66% by mass.
Life cycle description:	UF resins are thermosetting duromers and consist of linear or branched oligomeric and polymeric molecules, which also always contain some amount of monomer. Non-reacted urea is often beneficial to achieve special effects, e.g. better stability during storage. However, the presence of free formaldehyde is ambivalent. On the one hand, it is necessary to induce the hardening reaction. On the other, it causes formaldehyde emission during the press cycle as well as subsequent, displeasing, formaldehyde emission from the pressed boards, a fact that has led to a total change in the formulation of UF resins during the last 20 years. These days the problem of subsequent formaldehyde emission has been solved, at least in Europe, where the most stringent formaldehyde emission regulations in the world exist. Other countries have already followed, will follow or should follow this trend. After hardening UF resins form an insoluble, threedimensional network and cannot be melted or thermoformed again. In their stage of application UF resins are still soluble or dispersed in water or in the form of spray dried-powders, which, in most cases however, are redissolved in water for application.

		EVALUATION	
Domain	Metric	Rating	Comments
Process description:	The reaction of urea and formaldehyde is basically a two-step process: usually an alkaline methylation followed by an acid condensation. Methylation refers to the addition of up to three (four in theory) molecules of the bifunctional formaldehyde to one molecule of urea to give the so-called methylolureas. Each methylation step has its own rate constant, k_i with different k_i values for the forward and backward reactions. The reversibility of this reaction is one of the most important features of UF resins, and is responsible for both the low resistance against hydrolysis caused by the attack of moisture or water and the subsequent formaldehyde emission. This is so because emittable formaldehyde results from the slight hydrolysis of weakly bonded formaldehyde. The formation of methylol groups mostly depends on the F/U molar ratio, with higher molar ratios increasing the tendency to form highly methylolated species. Products of side reactions are acetals, hemiacetals and etherified products, with residual methanol always present in small amounts from the production of formaldehyde. The methylol groups are more or less stable in slightly alkaline conditions. Alkaline condensation might also occur to a limited extent, but this is of no industrial importance. Starting the reaction of urea and formaldehyde in the usual molar ratio but under acidic conditions gives methylene-linked ureas which tend to be insoluble in water with ca. five or six urea units. Methyleneureas are used as long-term fertilizers, as neutral fillers and as a white pigment, with some other ideas for industrial and commercial use still being at the development stage. The UF polymer builds up in the acid condensation step: the methylols, urea and free formaldehyde still present in the system react to give linear and partly branched molecules with medium and even higher molar masses. The type of bond between the urea molecules depends on the conditions used: low temperatures and only slightly acidic pH favour the formation of methylene ether bridges (-CH₂-O-CH₂-), while higher temperatures and lower pHs lead to the more stable methylene (-CH₂-) bridges. Ether bridges can rearrange to methylene bridges by splitting off formaldehyde. One ether bridge needs two formaldehyde molecules and it is not as stable as a methylene bridge. Hence it is recommended to avoid such ether groups in UF resins under today's common conditions of low formaldehyde content by virtue of the low final molar ratio of the resins. The acid condensation step itself is still performed at the same high molar ratio as given in the alkaline methylation step (F/U"1.8 to 2.5). Molar ratios lower than ca. 1.8 lead to some precipitation during the acid condensation step, causing inhomogenities in the solutions as well as problems in the determination of the proper endpoint of the reaction by water dilutability or by cloud point. The low molar ratio of the final UF resin is adjusted by the addition of the so-called second urea, which also might be added in several steps. Special knowledge of this step is important for the production of resins with good performance, especially at the low molar ratios usually in use today in the production of particleboards and medium-density fibreboards (MDFs). The production of UF resins is performed in a discontinuous as well as in a continuous way; the latter is useful only for the production of large batches to avoid too often the preparation of off-grade products. The reaction is influenced by several parameters and requires precise control of purity, amount and sequence of addition of the raw materials and of alkaline and acid catalysts. The preparation conditions are adjusted and monitored with respect to temperature, pH and concentration of the reactants. Usually, a three-stage process is used. The first stage is always the methylation step which is usually performed under alkaline conditions and at high molar ratio (F/U"1.8 to 2.5). This step is necessary to build up the different methylolureas, the types and proportions of the methylols formed being dependent on the F/U molar ratio. The polycondensation reaction takes place in the subsequent acid condensation step to form polydisperse patterns of oligomers and polymers of different molar masses. The determination of this molar mass distribution can be done by means of GPC. The molar mass distribution (according to the degree of condensation) is one of the most important characteristics of the resin and determines several of its properties, e.g. viscosity and flow behaviour, wetting behaviour of a wood surface and penetration into the wood surface. The last production step includes distillation of the resin solution usually to 65-66% solids content, which is performed by vacuum distillation in the reactor itself or in a thin layer evaporator. Before or after this step an addition of urea in one or more steps at different temperatures, including also maturing times, can take place in order to decrease the final molar ratio. Different examples for the production of UF resins are described in detail in the literature. During the curing process a more or less three-dimensional network is built up. This yields an insoluble resin that is no longer thermoformable. The hardening reaction is the continuation of the acid condensation step. Whereas gelling in the reactor is to be avoided, the same process needs to take place in the glue line. The acid conditions can be adjusted by the addition of a so-called latent hardener, or by the direct addition of acids (maleic acid, formic acid, phosphoric acid and others) or acid compounds which dissociate in water (e.g. aluminium sulfate). Common latent hardeners are ammonium sulfate and ammonium chloride. The latter, however, has not been used in the German and Austrian particleboard and MDF industry for several years now, because of the generation of hydrochloric acid during combustion of wood-based panels causing corrosion problems and the suspected formation of dioxins. Ammonium sulfate reacts with the free formaldehyde in the resin to generate sulfuric acid, which decreases the pH. This low pH and the ensuing acid conditions enable resumption of the condensation reaction and finally the gelling and hardening of the resin. The rate of decrease of pH depends on the amounts of available free formaldehyde and hardener, and is greatly accelerated by heat.

Production, import, or use volume:	8.5 billion lb in 1980 (pg 2) Large facilities: >140 million lb/yr; medium: 100-140 million lb/yr; small: <100 million lb/yr (Table 1, pg 1)			
Process description:	"Formaldehyde produced in the United States is manufactured by two general processes: one using a metal oxide catalyst, Figure 2; the other using a silver catalyst, Figure 3. These two processes are very similar except for the addition of a distillation column in the silver process to concentrate the aqueous formaldehyde to a usable concentration and to reduce the methanol content. Methanol, normally received from offsite, is transferred from storage tanks and vaporized in a vaporizer. Vaporized methanol, mixed with preheated air, enters the converter and is oxidized (or dehydrogenated and oxidized if silver catalyst is used) to formaldehyde. Typically, the converter has a packed-tube configuration, but catalyst beds are also used. Efficiency of conversion of methanol to formaldehyde range from 65 to 90% for the silver process and is approximately 99% for the metal oxide process (6). After conversion, the hot formaldehyde gas [the reactor is generally operated at approximately 635°C (6)) is cooled in an after-cooler to a temperature of about 70°C and then absorbed in water. Aqueous formaldehyde solution is recirculated through the absorption tower until the desired concentration is achieved. If a silver catalyst is used in the converter, the product is concentrated in a distillation column, a step in which methanol is also recovered. Formaldehyde is generally stored as a 50% solution at 50°C (which helps prevent paraformaldehyde formation)."

EXTRACTION				
Parameter	Data			
Production, import, or use volume:	FA is made in quantities > 1 million tons per year. Total FA production in Europe in 2015 was around 3.2 million tonnes (as 100% pure FA) which is equivalent to 8.6 million tonnes as 37% water solution. According to Eurostat (2018) data, FA imports into the EU from extra-EU countries were in the range of 20-30 thousand tonnes annually between 2015 and 2017, which accounts for less than 1% of the amount produced in Europe. Almost 98% of total FA produced or imported in the EU is used as an intermediate to produce formaldehyde based resins, thermoplastics and other chemical. Urea FA resins: 95% of UF resins are used in binders or adhesives in wood-based panels. Approximately 60% of phenol formaldehyde resins are used in the building and construction industry for applications including insulation binder, wood-based products and laminates, other end uses include automobile applications and foundry binders. Melamine formaldehyde resins are used widely in the building and construction industries in the form of laminates and surface coatings, which account for more than 95% of its consumptions with applications also in the automotive sector and for housewares. Around 60% of the whole amount of FA used in the EU is used in the manufacture of resins which are used to produce a broad range of articles for consumer use: manufacturing of wood-based panels as bonding agents which include plywood, particleboard, oriented strand board, medium density fibreboard, and other fibreboard. Also used in the production of other wood-based based products including furniture, flooring, and building elements for indoor and outdoor use. Remaining 40% of the FA manufactured and imported into the EU is used in the production of paints for industrial use, in the production of mineral wool, in the textile and leather industry, and in the production of foams for insulation of buildings and cars. Table 2 is a COU table for consumer uses.			
Life cycle description:	Formaldehyde is predominantly used as a chemical intermediate in the production of formaldehyde-based resins and other chemicals. The most common substances manufactured from formaldehyde include urea formaldehyde resins, phenol formaldehyde resins and melamine formaldehyde resins. Such formaldehyde-based resins are the biggest group of formaldehyde releasers, a broader group of substances with the common element that they can release formaldehyde under foreseeable conditions of use. Formaldehyde-based resins are widely used as adhesives and binders in the woodworking, pulp and paper, as well as the synthetic vitreous fibre industries, in the production of plastics and coatings, and in textile finishing.			
Process description:	At an industrial scale, formaldehyde is manufactured by catalytic oxidation of methanol via either a silver or metal-oxide catalyst process. Production capacity is split almost equally between the two processes. In the metal-oxide process, methanol is oxidised with excess air in the presence of a modified iron-molybdenum-vanadium oxide catalyst at 250-400 °C and atmospheric pressure (methanol conversion, 98-99%) (IARC, 2006). In the silver process methanol is directly converted into formaldehyde and hydrogen at 600-780 °C. Figure 1 presents an illustrative summary of the formaldehyde manufacturing process (metal-oxide conversion). At all sites formaldehyde manufacturing is integrated with the manufacturing of formaldehyde-based resins and/or other chemicals, representing the vast majority of the intermediate use of formaldehyde. In addition, ± 11 non-integrated sites produce large volumes of formaldehydebased organic chemicals – mainly methylene diphenyl diisocyanate (MDI) and polyols – and some others may use rather small quantities of formaldehyde to produce specialty chemicals. Figure 1 provides flow chart of FA manufacturing process

EXTRACTION	
Parameter	Data
Process description:	The garment manufacturing facilities surveyed during this study receive pre-cured finished fabric from a textile-finishing plant. The fabric is treated at the textile-finishing plant with methylolated(formaldehyde-based) resins to give the fabric crease-resistantcharacteristics (permanent press). The resin-treated fabric was cured before it was received by the garment plant.The first step in the process is the cutting of garment parts from the fabric. In order to do this, many layers of fabric must first be spread out, one on top of another, on a long table. All of the layers are then cut simultaneously with hand-held saws ("cutters") or with dies. When a hand-held cutter is used to perform this step, a pattern is first laid over the top layer and the operator cuts according to this pattern.After cutting, the garment parts are assembled. Individual parts (e.g. cuffs, collars, sleeves, etc.) are assembled into complete pieces, then the major pieces are assembled further into completed garments. Host of the various assembly operations require sewing with sewing machines appropriately modified for each type of operation. Some sewing operations in a plant, such as attaching of pockets to shirt fronts ("pocket setting"), have been "de-skilled". This means that a degree of automation has been utilized in the process. The workers position the parts to be sewn together onto the machines; the machines then hold the parts in the proper position and make the required stitches without further guidance from the workers. Other sewing tasks are accomplished with more conventional sewing machines. Several assembly operations make use of heat to form or fuse together (in conjunction with a heat-sensitive adhesive) various parts. Conventional hot electric irons are used to press the fabric in some locations. The following assembly operations apply heat to the fabric:1. Fusing of Lining to Collar: The adhesive-coated lining and the collar are heated to approximately 320°F (160°C) and rolled together, which fuses them.2. Collar Forming and Pressing: The operator forms the collar with fabric on a specialized machine, and the machine presses the collar at a temperature of 300-350°F (149-176 0 C) to give it permanent shape. 3. Collar Band Creasing: Prior to the assembly of the (collar) bands, the bands are formed to specific shapes and heat is applied to maintain those shapes.4. Label Attach: The labels are fused to the shirts by applying heat[about 400°F (2040 C») to the heat-sensitive adhesive which is on the labels. The fusing method of label attach is currently used to avariable extent across garment plants and intermittently in some plants; labels are sewn on in other plants or at other times.5. Re-do Collar Press: This pressing machine, set for 300-310°F(149-1540 C), is often used to re-press collars which are wrinkled.6. Hand Ironing of Collar Bands ("Re-do"): Conventional irons are used to re-press wrinkled bands.7. The completed garment may then be pressed (in some facilities) on steam applied apparel presses as the final finishing step. Finished garments are moved to an area where they are properly folded for packaging. When the cuff will show in the package, it is pressed in this area. The fronts and collars also are pressed with hand irons as necessary. The garments are packaged in boxes or bags and are ready to ship. These process operations are typical of the garment manufacturing industry. No substantial changes in the garment manufacturing process from 1955 to 1985, other than improved resin systems, were identified which could have affected formaldehyde exposure levels. (P. 14/58)

Process description:

The Urea-Formaldehyde Foam Insulation SystemManufacturing ProcessA two-component urea formaldehyde foam insulation system, consisting of a resin and a foaming agent, is made at each of these facilities. The manufacturing process and the chemical components of the urea formaldehyde-based system at Manufacturer B have recently been patented;however, the patent number is not yet available.Manufacturer ATwo batches of urea formaldehyde resin are made daily in a 1500-gallon rectangular stainless steel reactor. The bottom of the reactor is heated directly with open propane gas burners. The reactor is vented through a stack equipped with a double-reflux condenser at its base. There is a small rectangular access door on the top side of the reactor for batch sampling. Formalin (37 percent formaldehyde in water inhibited with a maximum of 1 percent methanol) is piped directly to the reactor from a large storage tank located in the west end of the production area. The pH of the formalin is then adjusted with sodium hydroxide. Simultaneously, prilled urea is augered into a cylindrical stainless steel kettle and dissolved in warm water. This vessel, known as the addition tank, is also gas-heated and is located near the reactor. Water and aqueous ammonia are added to the reactor and the pH of the solution is adjusted with sodium hydroxide. The reaction proceeds until a predetermined degree of condensation has been reached; at that time, the urea solution is pumped from the addition tank into the reactor. After an additional required degree of condensation has been reached, the pH of the resin is adjusted with sodium hydroxide and the resin allowed to cool. When the resin has cooled to a specified temperature, a fire retardant, an anti-shrinking agent and a humectant are added; these are proprietary materials. In addition, a cross-linking agent (furfuryl alcohol) is added. The batch of resin is then piped from the reactor into a 2000-gallon holding tank. A hose attached to the holding tank is used to convey the resin from the tank into 55-gallon plastic drums. The drums are either filled with the lid off or, more frequently, through the lid opening. The foaming agent, or "B" component, is blended in the southwest section of the production area. The main ingredient is a proprietary blend of "cross-linking and emulsifying agents" purchased by the company; it is received in large plastic drums and pumped into a 2000-gallon tank. Proprietary hardeners, a proprietary catalyst, and water are added andblended to form the foaming agent "concentrate"The foaming agent is dispensed through a hose into 55-gallon drums and through a spigot into 5-gallon plastic pails. One of the hardeners is added directly to the 5-gallon pails. Manufacturer BBatches of resin are made in a 2750-gallon reactor. The productionschedule varies with demand for the product from the installers, ranging from two to ten batches per week. The reactor, which is heated and cooled by piping water through a system of coils, vents through a reflux condensor. The reactor is charged with base materials consisting of a methylolurea prepolymer, small amounts of acetaldehyde, urea, and phenol in an aqueous solution. The base materials are piped directly to the reactor from storage tanks in the production area. Small amounts of phenol and prilled urea are added to adjust the composition of the reaction mixture and the mixture is heated with constant agitation. Formic acid solution is added and the reaction proceeds until the proper degree of condensation is reached. The reaction is stopped with sodium hydroxide and cooled, and additives including fructose and urea solution are introduced. The finished resin is piped through a hose from the bottom of the reactor into 55-gallon metal drums. The drums are filled through the lid openings. The foaming agent is manufactured in batches of approximately 2300gallons. Generally, one batch of foaming agent is made for each batch of resin produced. Foaming agent is manufactured by mixing a sulfonic acid emulsifier containing small amounts of sulfuric acid, and oxalic orphosphoric acid with water. The emulsifier is a proprietary compoundpurchased by Manufacturer B, and the use of oxalic or phosphoric acid is determined by the ambient temperature at the location where the product will be applied. Mixing continues at room temperature for approximately 6 hours, after which the foaming agent is transferred to 55-gallon drums.The Polyurethane Foam Insulation System Manufacturing ProcessRigid polyurethane foam systems for thermal insulation consist of an "A" and a "B" component which, when mixed, form a rigid foam. The 11A11 component consists of a mixture of polymeric (50%) and monomeric (50%) methylene bisphenyl isocyanate (MDI), which is purchased in bulk and repackaged into drums. Alternately MDI may be blended with a flame retardant and then drurraned.The "B"component, or resin, is a mixture of ingredients which are prepared by a blending process. The process does not involve a chemical reaction. The formulation of a resin may vary depending upon the end use of that product. Resins produced by both manufacturers are intended for a variety of uses, including thermal insulation.The resins used for thermal insulation contain one or more polyols (polyhydroxy compounds), a silicone oil copolymer, one or more tertiary amine catalysts, an organotin catalyst, Fluorotrichloromethane (used as a blowing agent), and alpha-methyl styrene (used as a stabilizer). A phosphate ester-based flame-retarding agent may also be added.Manufacturer CThe MDI repackaging process at this facility is conducted several times per week, as needed, and usually involves only one employee. Twenty to fifty thousand pounds (40-100 drums) may be drummed per day. This operation takes place inside a 100 1 x 290 1 building which also serves as a warehouse. The bulk MDI tank car is located adjacent to this building; there is a permanent pipe connection to the MDI loading area. In the resin manufacturing process any one of several various sized vessels may be used. All of the vessels are located inside the 40 'x 50 'compounding room. Raw materials, including polyols, silicone oil copolymers, and fluorotrichloromethane are poured from drums into the top opening of the vessel using an electric drum lifter. Ingredients are measured by weighing each drum before and after pouring. Ingredients are mechanically stirred until homogeneous and then sampled for quality control. After

EVALUATION			
Domain	Metric	Rating	Comments
Process description:	The Urea, Formaldehyde Foam Insulation SystemApplication ProcessApplicator AExterior Retrofit Applications Manufacturer A's foaming agent is received in 5-gallon plastic pails (2.5 gallons per pail) and the resin in 55-gallon plastic drums. Prior to use, the foaming agent is diluted with water to 55 gallons. The resin and foaming agent are stored in the warehouse along with other insulation materials, mortar mix, and application equipment. The warehouse is a one-story, 2500-square foot structure situated adjacent to the office. It also serves as a vehicle storage garage and as a location for rebuilding application equipment. Application equipment is rebuilt as time permits. Applicator A has three urea formaldehyde foam application crews. The urea formaldehyde foam application 'crew usually consists of five individuals—one Foam Mechanic and four Laborers. The Foam Mechanics are certified applicators of Manufacturer A's urea formaldehyde foam. Certification is awarded by Manufacturer A after a 1-week foam application training course. The crew members arrive at the office at 7:00 a.m. Job sites are designated by the production manager. The crews leave the warehouse area between 7:15 a.m. and 7:45 a.m. in three 12-foot step vans. There is a partition between the front and back sections of one of the vans. The vans are stocked with the necessary supplies and equipment on the preceding evening. Upon arriving at the job site, a determination is made of the appropriate method for gaining access to the wall cavity, which is generally referred to as "opening" the structure. Masonry is drilled, aluminum siding and shingles are removed, and weatherboard is knocked through with a hammer. The holes are made between studs and fire-stops. The resulting openings are relatively small—3/4 inch in masonry and 2-3 inches in weatherboard. The building is opened by the four Laborers and, when he is not performing other duties, by the FoamMechanic.While the building is being opened, the Foam Mechanic cleans the application gun and hose, and starts circulating resin and foaming agent. The resin and foaming agent circulate from storage drums through plastic tubing and a pump and back into the drums. This is done to assure a uniform product. Application equipment components downstream of the foaming chamber usually cake with dried foam. The components are disassembled with a wrench and cleaned with hot water and a rag or by scraping with a tool such as a screwdriver. Some Foam Mechanics choose to clean their equipment in the afternoon, following completion of foam application for the day.Foaming begins after the structure has been opened to a point where foam application can proceed without interruption, the application equipment has been cleaned and reassembled, and the resin and foaming agent have been properly circulated. Before the foam is applied, a density determination is made. This is accomplished by filling a standard volume with foam and weighing. Resin, foaming agent, or nitrogen adjustments are made until the foam density is within an acceptable range. Foam is also discharged onto the ground so that foam body can be evaluated. This is known as making "beehives" due to the appearance of the resulting pile of foam. Occasionally, a piece of the foam is tasted as part of the qualitative testing.After the foam has passed the qualitative and quantitative tests,application begins. Figure 1 is a drawing of the foam applicationsystem. The application gun is suspended from the Foam Mechanic's shoulder by a strap. The application hose, located on the end of the application gun, is inserted into the wall opening. A lever on the gun is depressed, and proper amounts of nitrogen and foaming agent mix in a chamber with plastic beads. The nitrogen serves as a blowing agent. Downstream of the mixing chamber, resin is introduced. The resulting foam, similar in appearance to shaving cream, leaves the application hose and fills the wall cavity. After the space has been filled, a Laborer removes the excess foam from the wall with water from a garden hose. The hole is then "closed" (i.e., covered, plugged, or filled) by another Laborer. For example, shingles are nailed back into place, masonry is filled with a small amount of mortar, and aluminum siding is put back into place. On occasion, one employee is stationed in the house to listen for structural stress caused by overfilling the wall cavities. After all the cavities have been filled, the Foam Mechanic cleans the application equipment (if that is his preference) and stores it in the van. He then sketches and measures the square footage of the structure to check the measurements previously made by the salesman. In the meantime, the Laborers finish closing and clean waste material from the area. The trash is placed in the back of the van in plastic bags. The crew's workday ends when they return to the warehouse. At the warehouse, waste material is disposed of into a dumpster, and the van is stocked with adequate foaming agent and resin for the next day. This is done by the Warehouseman. Open-Bay ApplicationIn this procedure, the urea formaldehyde foam is applied between exposed studs before the wallboard is put into place. Usually, small amounts of the foam are first "splattered" onto the surface. This is accomplished by increasing the nitrogen pressure and pinching the end of the application hose. After the form has been splattered, the nitrogen pressure is reduced and a rectangular, transparent piece of plastic is placed on the end of the application hose. There is a hole in the plastic to allow foam to flow through it. The plastic bridges the two adjacent studs and serves as a trowel as the foam is applied from floor to ceiling in the cavity. Good foam body prevents the foam from falling out of the cavity. The foam slightly overfills the cavity. A flat-edged shovel is used to bridge twoadjacent studs and scrape the excess foam off and onto the floor. This is done by a Laborer approximately 15 minutes after the cavity has been filled with foam. Normally, a third Laborer nails a polyethylene sheet over the insulation. Other aspects of open-bay application activities are similar to exterior retrofit application activities.Applicator BExterior Retrofit ApplicationThe resin and foaming agent are stored in the warehouse, which is an 11,000-square foot, one-story stone structure. Other items stored in the warehouse include: cellulose insulation, cellulose insulation adhesive, commercial mortar mix, muriatic acid, and application equipment. In addition to being a storage area, the warehouse also serves as a shop for performing light maintenance on equipment. Occasionally, foam is tested by discharging foam onto the warehouse floor. Generally, the application team consists of the company president's two sons; both have been certified by Manufacturer Bas foam applicators. A third individual is utilized for large jobs. The application team arrives at the warehouse about 8 a.m. and loads a 12-foot step van with the application equipment and insulation components. About 8:15 a.m., the application team leaves the warehouse for the job site.Applicator B's opening, circulating, equipment cleaning, and foamapplication processes are similar to Applicator A's with a fewexceptions. Applicator Buses air compressed by a gasoline-powered compressor instead of compressed nitrogen. The application gun used by Applicator B differs from Applicator A's in that the blowing agent and foaming agent do not mix in a chamber containing plastic beads. After all the cavities have been filled, the application equipment is put away. The applicator then assists in closing operations. At the end of the day, trash foam is put into plastic bags and placed in the van. The application team then returns to the warehouse to store equipment, dispose of trash, and perform maintenance on equipment if necessary.Open-Bay ApplicationInitially, the

Process description:	Plastic products manufacturing involves molding, forming, shaping, or otherwise altering plastic resins or plastic materials to produce an intermediate or final product. This manufacturing industry is also commonly referred to as plastics processing or polymer processing. The manufacture of resins is not a part of plastic products manufacturing; however, some facilities manufacture resins at the same site as where the resins are processed. Solid and foamed plastic products are manufactured using plastic resins or solid plastic chips as the starting material. Most plastic products are manufactured by mixing plastic resins with additives, applying heat or pressure to the mixture, and shaping the mixture to form the desired product. Types of Plastics Plastic products can be fabricated into a solid or foam state. The basic properties of a plastic product are influenced and limited by the physical and chemical characteristics of the plastic resin from which it is made. Plastic resins are generally defined by their rheology, or ability to flow under heat or pressure. Thermoplastic resins (or dry blends) and thermoset resins are the two major classes of resins that are used to manufacture plastic products. Although most resins fall into one of these two classes of resins, some resins can be classified as both a thermoplastic and thermoset resin. Thermoplastics Thermoplastic resins (or thermoplastics) are plastic resins that will repeatedly become soft when heated and hard when cooled. Thermoplastics do not normally undergo a chemical change during forming. Plastic products manufacturing facilities usually purchase and use thermoplastics in solid pellet form for processing. An economic advantage of products made from thermoplastics is that they can be easily remanufactured or reprocessed. Thermoplastics account for the major share of domestic polymer production. The following six thermoplastics are processed in the largest quantities in the United States: Low-density polyethylene; High-density polyethylene; Polyvinyl chloride; Polypropylene; Polystyrene; and Linear low-density polyethylene. Thermosets Thermoset resins (or thermosets) undergo a chemical reaction and become permanently solid when heated, pressurized, or reacted with a hardening agent. Thermosets are usually available in liquid or powder form for processing. Unlike thermoplastics, thermosets cannot be easily remelted or refabricated. However, scraps from thermoset processing operations can be used as fillers for other products. Some widely used thermosets include: Epoxy; Phenolic; Unsaturated polyester; and Urea. Foamed Plastics Foamed plastics (or foams) have a unique cellular structure that is different from solid plastics. For this reason, foams are often called “cellular plastics.” Foams, which are rigid, semi-rigid, or flexible, can be manufactured with thermoplastic or thermoset resins. Many of the manufacturing techniques used to fabricate solid plastic products are also used to make foam products. The process used to manufacture foams influences the properties of the final foam product. Some typical foams include: Polystyrene foam; Polyurethane foam; and Polyethylene foam. Manufacturing Techniques Solid and foamed plastic products are manufactured by a variety of methods. The choice of manufacturing techniques used to process a plastic product depends largely on whether the resin is a thermoplastic or thermoset, and the dimensions, shape, or physical qualities of the desired product. Extrusion is the most widely used processing technique, followed by injection molding, blow molding, and foam processing. Extrusion The extrusion process is a common technique used to form thermoplastic materials into long plastic shapes including pipes, tubes, coated wires, coated cables, rods, and continuous sheets and films. The types of extrusion methods are as diverse as the products that can be fabricated by extrusion. Extrusion methods include blown film, sheet extrusion, cast film, extrusion coating, profile extrusion, pipe and tubing extrusion, wire and cable coating, and fiber extrusion. In most extrusion operations, dry resin material is poured into a hopper, which directs the resin material into the feed throat of the extruding machine where the resin is heated. A large continuously revolving screw encased in a long heating chamber then carries the heated resin down the length of the screw toward a die (orifice) at the end of the chamber. The revolving screw forces the fluidized resin material through the die which has the shape of the cross section of the final plastic product. After the resin material exits the die, it may be wound into a roll, or transported on rollers or a conveyor belt where it is cooled by air or water immersion. Molding In most molding operations, the forming of the intermediate or final plastic product takes place in a closed mold. Molding methods vary depending on resin type, raw materials, desired plastic product shape, and other factors. Some of the more typical molding methods include injection, blow, general, rotational, transfer, reaction injection, and compression injection. Injection Molding Injection molding is one of the more common methods used to mold thermoplastics; however, this method can also be used to mold thermosets. The injection molding process is similar to the extrusion method except that in injection molding, the molten material is injected into a mold rather than forced through a die. Plastic pellets are fed into a heating chamber and are pushed along by a plunger until they are homogenized and fluidized. The fluid plastic is then injected (forced under high pressure) through a nozzle into a relatively cold mold. The fluid plastic conforms to the shape of the clamped mold, which is released once the plastic solidifies. The reciprocating screw injection machine, which serves as both a plasticizer and injection ram, is the most common machine used for injection molding. Reaction Injection Molding is a recently developed injection molding technology that mixes liquid plastic (i.e., polyols and isocyanates) at low temperatures before injecting the liquid plastic into a mold. Unlike standard injection molding, an exothermic reaction takes place in reaction

HERO ID:	2452610
Conditions of Use:	Firefighting

EXTRACTION	
Parameter	Data
Process description:	Exercises involving smoke simulant are conducted to train fire fighters on proper fire-attack and victim-rescue techniques in low visibility conditions inside the training tower. The training rooms on each floor had different obstacles, all made of steel. The first floor training room had a stove, the second floor training room had a bed, and the third floor training room had a desk. A built-in MDG Fog Generator System generated the oil-based smoke simulant. This system was controlled remotely from a nearby classroom. MDG Neutral Fluid was heated (maximum of 140 degrees Fahrenheit [°F]) in an external reservoir and pressurized (50 pounds per square inch). It was then transported along with pressurized nitrogen sheath gas (50 pounds per square inch) to the training rooms on each floor. The gas and fluid terminated at the nozzle in each room to produce airborne oil-based aerosol with a reported particle size of 0.5 to 0.7 micrometers (μm). In addition to the oil-based smoke simulant, the fire department occasionally used a glycol-based smoke simulant. Portable fog machines (High End FQ-100) generated the glycol-based smoke simulant. Glycol-based fluid was poured into the machine, heated, and aerosolized into the training room. The portable fog machines are less expensive to operate than the built-in oil-based fogging system; however, the portable units require longer periods to reach a smoke saturation point necessary for training exercises. After generating oil-based smoke simulant, glycol-based smoke simulant, or both, the fire department also occasionally (35%–40% of the time) used propane burners and heaters to generate rollover fire conditions inside the training room. This process was controlled remotely from the nearby classroom. Exercises involving heat and fire were intended to mimic conditions that a fire fighter may encounter in the field, including temperatures above 400°F.

HERO ID:	1963424			
Conditions of Use:	Use of Paper Products			
EXTRACTION				
Parameter	Data			
Life cycle description:	Melamine-formaldehyde (MF) and melamine-urea-formaldehyde (MUF) resins are used to impregnate paper for the manufacture of both high pressure and particularly low pressure laminates (Pizzi 1983, 1994). After the preparation either of the impregnated paper or of the final laminate at the hot press a considerable amount of paper impregnated with non-fully-cured melamine resins is produced by square-trimming the paper. The amount of this dry waste is considerable, running up to 400 tons/year in just a medium sized paper impregnating factory (Botcher 2002, personal communication).			
Chemical concentration:	This powder is composed of cellulose (~50%), melamine (~40–50%), some urea and some formaldehyde linked to the melamine.

EXTRACTION				
Parameter	Data			
Chemical concentration:	untreated cotton fabrics: <2 ppm (pg 3); ""To determine if there was irreversible adsorption of formaldehyde to untreated, cotton-based fabrics, several types of test fabrics were fortified with known amounts of formaldehyde solution (1 $\mu\text{g}/\mu\text{L}$). Average recoveries of formaldehyde from both mercerized, combed-cotton broadcloth samples and the control samples were 85.8 +/- 5.2 percent and 85.5 +/- 4.3 percent, respectively (6 samples per level; 3 levels), and were equivalent at all three concentration levels. The less than stoichiometric recovery for these samples, including the reference samples, is probably due to loss of formaldehyde into the headspace of the sample vial. With the polyester/cotton broadcloth, the recovery was dependent on loading. At 10.6 $\mu\text{g}/\text{sample}$, recovery was 0.6 & 0.7 percent. Recovery increased to 45 +/- 3.4 percent and 77.8 +/- 3.8 percent at 107 and 1186 $\mu\text{g}/\text{sample}$ "" (pg 5) ""The control samples contained 183.8 +/- 6.5 μg of formaldehyde, as determined by the chromotropic acid method. The same samples, when analyzed using the 2,4-DNP method, contained 174.8 +/- 3.6 μg of formaldehyde. The samples exposed to formaldehyde vapor contained 2137 +/- 250 μg (chromotropic acid method) and 2082 +/- 240 μg (2,4-DNP method).... [after exposure to ambient air for 1 hour to study loss of absorbed FA] The total amount of formaldehyde found for each sample was 1734 +/- 228 μg of formaldehyde"" (pg 6)

Production, import, or use volume:	Annual worldwide production capacity now exceeds 15 X 106 t (calculated as 37% solution). The United States, Canada, Europe, and Japan account for nearly 70% of the total capacity.			
Life cycle description:	Formaldehyde is a basic chemical building block for the production of a wide range of chemicals finding a wide variety of end uses such as wood products, plastics, and coatings.			
Process description:	Following World War II, as much as 20% of the formaldehyde produced in the United States was made by the vapor-phase, noncatalytic oxidation of propane and butanes. This nonselective oxidation process produces a broad spectrum of coproducts which requires a complex costly separation system. Hence, the methanol process is preferred. The methanol raw material is normally produced from synthesis gas that is produced from methane. Most of the world’s commercial formaldehyde is manufactured from methanol and air either by a process using a silver catalyst or one using a metal oxide catalyst. Reactor feed to the former is on the methanol-rich side of a flammable mixture and virtually complete reaction of oxygen is obtained; conversely, feed to the metal oxide catalyst is lean in methanol and almost complete conversion of methanol is achieved.

HERO ID:	4794995			
Conditions of Use:	Other-Insect Rearing			
EXTRACTION				
Parameter	Data			
Process description:	The moths reared at this facility were sterilized by irradiating them with cobalt 60. Sterile moths were subsequently released from aircraft into cotton fields as the Sterile Insect Technique component of the International Pink Bollworm Eradication Program. At the time of evaluation, between 20 and 26 million moths were produced daily during the cotton growing season; the facility was designed to produce approximately 15 million moths daily. Smaller numbers of moths (approximately 300,000 per day) were reared during the off season to maintain a continuous supply of bollworms on the basis of the lifecycle shown in Figure 1. Moth production was divided into two areas: “dirty” and “clean.” The dirty area refers to the part of the PBWRF where scales from moth wings (moth scales) were released during operations. The dirty area was maintained under negative pressure relative to surrounding areas to contain moth scales. The clean area refers to locations within the PBWRF where adult moths and scales should not be found. This arrangement was necessary to protect the health of the moth colony and ensure adequate moth production. Appendix B provides long detailed process descriptions of all work areas.

EXTRACTION	
Parameter	Data
Process description:	BookbindingThe printing of the pages is accomplished off-site. Signatures (the printed page sections) arrive at the facility from the printers. Six varieties of hot-melt glues are used in nine machines on threefloors of the main facility to produce finished volumes. The hot-melt glues arrive in solid pellet form and are preheated in gas-fired, pre-melt pots near the points of application.The liquified hot-melt glues are then piped to the respective points of application, where they are heated further and applied at approximately 350 F. Hot-melt glues are used in these machines:Kolbus Tipper, UB4 and UB5 binders, Compact 45, 3 Kolbus Liners, End Paper Combiner, and Crathern Casemaker. On the second floor, the Kolbus Tipper places end leaf pages onto the first and last signatures. The signatures are then loaded into gathering machines on the first floor which assembles them into sequential order. The ordered signatures pass through the UB4 or UB5 binder, where hot-melt glue is applied to bind them together. Combustion of natural gas is used to speed the drying of the hot-melt glues between operations. The bound signatures are trimmed to book size. A vacuum system picks up the scrap paper at the point of liberation and carries it to the baler area where the scrap is deposited into either one of two large rooms (about 300 yd3 each) above the baler. Other processes throughout the facility are involved with producing various types of covers. In the basement, two Cloth Cutter machine operators prepare cloth to selected widths; the Crathern Casemaker operator produces laminated cloth hardcovers; four Kolbus and Chandler-Price Stamper machine operators use heated plates (300 F) to apply metal foil designs onto covers; and the Dexter machine produce laminated paper covers. On the ground floor, three Kolbus Liner machines add reinforcement to hard covers. At the End Paper Combiner, liners for hard covers are cut. The Compact 45 machine places these covers and single-sheet "dust covers" onto the trimmed signature bundles as the final step in producing the finished volume. The finished books are stacked onto pallets for packaging and shipment.A shrinkwrap operation wraps clear plastic sheeting around pallets stacked with books, book boards (stiffeners which separate and reinforce signature bundles during shipment to the facility), and other materials before shipment from the facility. A propane torch is used to shrink the sheeting. The shrinkwrap operation is only performed on the day shift and requires about 20-30 minutes per day.Natural gas fuels the pre-melt pots and is also burned at the binding machines (UB4 and UB5) to speed the drying ofthe hot-melt glue between operations.
Throughput:	About 1,000 pounds of hot-melt glues are used to produce 100,000 hard cover and 25,000 paperback books each day.

Study Citation:	Gonzalez-Garcia, S., Feijoo, G., Widsten, P., Kandelbauer, A., Zikulnig-Rusch, E., Moreira, M. (2009). Environmental performance assessment of hardboard manufacture. International Journal of Life Cycle Assessment 14(5):456-466.		
HERO ID:	1697561		
Conditions of Use:	Compressed Wood Product Manufacturing		
EXTRACTION			
Parameter	Data		
Life cycle description:	Incorporation into an article - hard board manufacture		
Process description:	Subsystem of wood preparation - The main raw material is green wood chips from mostly Norway spruce (Picea abies) and European beech (Fagus sylvatica) delivered by truck wood-based industries such as sawmills, satellite chip mills, etc. Initially, wood chips are washed to remove dirt and other debris. Clean chips and additional raw material from the plant (sanding dust, sawdust, trimmings, rejected hardboard etc.) are reduced into fibers and resinated (optional) and placed in a storage bin. Part of the wood material is burned in biomass boilers to produce thermal energy for the plant activities. Subsystem of board forming - Fibers (with or without resin) are transported from the storage bin to the forming machine where they are deposited onto a moving conveyor and formed into a mat. The mat is pre-pressed and trimmed before being loaded into the hot press. This press applies heat and pressure to cure the resin and bond the fibers into solid boards. Usually, the press uses a multi-opening batch press and is heated (to ~200°C) by steam produced at the thermal energy plant. Subsystem of board finishing - After pressing, the boards are placed in a conditioning room and then fabricated by sanding and sawing into final size. Finally, the boards are packaged and sent to the warehouse for delivery to consumers. Trimming residues are recycled back to board production or used for on-site energy production. Ancillary activities - Several auxiliary activities were included within the system boundaries. Phenolic resin, paraffin emulsion and other chemicals production were part of the subsystem of wood preparation.

EXTRACTION				
Parameter	Data			
Life cycle description:	Formaldehyde is manufactured and made available as 30%-50% solutions. It may be refined or converted to a polymerized white powder or flake known as paraformaldehyde, which slowly releases gaseous formaldehyde.			
Chemical concentration:	Most formaldehyde is available as 30% to 50% solutions with buffers to inhibit intrinsic polymerization. Formalin, a commercial preparation, is a colorless 37% aqueous solution of formaldehyde.

HERO ID:	5954949			
Conditions of Use:	Wood Product Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The pilot plant consists of two enclosed production halls, A and B, where several machines are installed (see Figure S3). Hall A has a dimension of 30 m × 10 m × 7 m (L × W × H), and was used for sawing, flaking, cross hammer mill, chipping and sieving. Hall B has a size of 35 m × 15 m × 7 m (L × W × H). The processing’s including drying, refinery, gluing and pressing were carried out in Hall B. Particles were measured in the pilot plant for processing including sawing, flaking, cross hammer mill, chipping, sieving, drying, refinery, as well as gluing, forming and pressing. Four common woods of birch, oak, beech and pine were processed. Three types of wood board (medium density fiber board (MDF), oriented strand board (OSB) and particle board) were produced from each wood type. During a processing cycle, the particle instruments were placed next to the production site at a distance of about 1.5 m. It was chosen to represent the exposure situation of the machine operator. The online particle measurement was started before the processing to obtain the particle background concentration. Four types of woods were processed one after another. There was a break between processing each wood, which allows the emitted particles to disperse and the concentrations to decrease. When the processing finished, the instruments kept measuring for 30 min or until the concentrations decreased to the similar level as background concentration. A detailed protocol was kept recording the sequences ofprocesses (start, processing, end, break, cleaning etc.) and any other activities that may influence the particle concentrations. The pilot scale wood processing may reflect the situations in a carpentry or in a DIY workshop.In the wood-based panel factory, we carried out the measurements at five production sites including wood chipping, refinery hall, MDF form station, MDF press station, and MDF sanding & cutting station.

HERO ID:	1320761			
Conditions of Use:	Multiple			
EXTRACTION				
Parameter	Data			
Process description:	Frozen rolls of phenol-formaldehyde resin-impregnated fiberglass are taken from a deep-freeze and thawed. Strips of this material are cut, baking film is removed, and the material is laid up by hand and tools in multiple layers. Vacuum bags are applied over the lay-up and the air is evacuated from the layers. Under vacuum, the parts are oven cured at 250oF for 90 minutes. The parts are then cooled, debagged, and moved through trimming, deburring,sanding, and inspection stations. The surfaces of the parts are prepared, and the parts are painted, wrapped, and shipped.Phenol-formaldehyde resins obtain their commercially useful structural properties as a result of a polycondensation type of chemical reaction. "In polycondensation, two or more starting materials react with each other to build up the molecular structure. The initial polycondensation reaction is interrupted at a stage in which the prepolymer possesses properties that are desirable for further processing in the molding phase. The resins are sometimes referred to as "prepreg" materials at this stage of the process. The phenolic resins that were in use at Boeing are a class of resins known as thermosets, which means that they harden when heated and cannot be reformed after obtaining their desired shape. Because these resins are a "prepreg" material which has already gone through partial polymerization prior to being brought into the lay-up area, off-gassing from some of the unreacted starting materials may occur. Particulate exposures, however, are not of concern based on the physical properties of the material at this point. Particulate exposure may occur after the material has been cured and operations such as trimming and sanding begin.

HERO ID:	5966866			
Conditions of Use:	Building and construction materials (particleboard)			
EXTRACTION				
Parameter	Data			
Process description:	Hygrothermally treated and untreated L. philippiana particles were employed. The percentage of wood in the outer layer was 30 % and in the inner layer 70 %. UF (50 % solid) produced by Georgia Pacific Corp. with a molar ratio of 1:1.22 was applied as adhesive. This is a high emission resin, and was used without formaldehyde scavenger and without hardener in order to best determine the variation in formaldehyde release due to hygrothermal treatment. Particleboards with nominal densities of 600, 625, 650, 675 and 700 kg-m-3, with dimensions of 53 x 53 cm and 15 mm thickness were produced. The adhesive was applied at 8 % loading (dry basis) spraying it in a Drais FSP-80 blender. Pressing was conducted in a Bürkle LA-160 press at a temperature of 180 °C for 180 s. The maximum pressure used was 3 N-mm-2 for 30 s and half pressure of 1.5 N-mm-2 for 150 s. Two boards were produced for each nominal density, a total of 10 boards with non-treated particles and 10 boards with treated particles. (pg 3)			
Chemical concentration:	UF (50 % solid) produced by Georgia Pacific Corp. with a molar ratio of 1:1.22 was applied as adhesive (pg 3)

Study Citation:	Harrison, G.A. (1968). The sterilization of the respiratory circuits of automatic ventilators using formaldehyde vapour. Medical Journal of Australia 2(5):212-216.
HERO ID:	1315176
Conditions of Use:	Non-TSCA

EXTRACTION

Parameter	Data
Process description:	Two methods can be used to sterilize a ventilator with formaldehyde. First, the whole ventilator may be introduced into a container (usually plastic) which has been filled with formaldehyde vapor. The container is usually filled with formaldehyde by running in a flow of oxygen or air which has bubbled through a bottle containing formalin solution. Second, the ventilator can be turned on to cycle regularly and the gas stream made to pass through liquid formalin. The formaldehyde vapor then passes into the ventilator, achieving a constant concentration. (2/5)
Chemical concentration:	A 40% formalin solution is used for sterilization. (2/5)

EXTRACTION				
Parameter	Data			
Process description:	"Polymeric Resin Treatment: Polymeric resin wastewater treatment processes make use of adsorption and ion exchange mechanisms to remove pollutants from the wastewater. Resin columns are commonly employed; they are reactivated after completion of the treatment cycle by means of acid or alkaline solutions. It has been reported that weakly basic ion exchange resins, based on a phenol/formaldehyde matrix, are superior in treating pulp and paper bleach plant effluents. Prior to resin treatment, it is advantageous to screen and filter the waste streams and adjust the pH to 2 or 3. The resin adsorption approach is being pursued by three companies: Billerud Uddeholm, Rohm and Haas, and Dow Chemical Company. The Rohm and Haas and the Dow Chemical processes are at the pilot plant stage. The Billerud Uddeholm color removal process has been operated as a full-scale batch process in Skoghall, Sweden, since 1973. Based on the experience gained through operation of the full-scale system in treating the caustic first extraction stage effluent (E1) treatment was expanded to include chlorination stage washer effluent (C1). The first full-scale continuous installation began in December of 1980 at Skoghall, Sweden. In this system, a full countercurrent wash is used, and the effluent from the E1 stage is reused on the C1 stage washer after color and toxicity removal through the application of resin adsorption. The pollutants may be removed from the resin by elution with caustic or oxidized white liquor. The eluate at 10 percent concentration is mixed with the weak black liquor to be evaporated and burned in the recovery boiler. The resin is reactivated with the chlorination effluent. The chlorination stage effluent reactivates the resin is simultaneously decolorized and detoxified. The total mill BOD5 load is reduced by 30 percent and the color load by 90 percent. The Rohm and Haas process involves the use of Amberlite XAD-B resin decolorize bleaching effluent after filtration. The resin can be reactivated without the generation of waste sludge. This reactivation may be accomplished by using mill white liquor."

EXTRACTION			
Parameter	Data		
Life cycle description:	Formaldehyde is present in the exhaust of both petrol and diesel-fueled vehicles as a result of the incomplete combustion of the fuel. Formaldehyde is formed from the photochemical oxidation of many of the reactive hydrocarbon species emitted from motor vehicles. Formaldehyde is mainly removed from the atmosphere by photolysis and reaction with hydroxyl radicals. Neither dry nor wet deposition are important removal processes. Formaldehyde emission rates may decrease under cloudy conditions because the secondary formation from other organics is slowed.

HERO ID:	6558536			
Conditions of Use:	Autobody repair and painting			
EXTRACTION				
Parameter	Data			
Process description:	Before the cars are painted, structural damage to the cars is repaired elsewhere in the shop. This involves the repair and replacement of damaged parts. For some jobs, abrasive blasting with sand that contains crystalline silica is used for paint removal. This abrasive blasting was conducted in the open. After the cars have been repaired, they are brought to the paint shop. There is some sanding of areas to be painted. Parts of the car which are not to be painted are protected with masking. The car and autobody parts are painted in either the spray painting booth or in the vehicle preparation station. Generally, the vehicle preparation station is used only for small paint jobs or for primer painting. After the car or body part has been painted, the worker leaves the booth and the paint is cured at a temperature between 120 and 140°F. In this shop, spray painting is performed using gravity-fed, HVLP spray painting guns. The air pressure at this point is less than 10 PSI. In this shop, most painting jobs involve the application of a primer, base coat, and a clear coat.

EXTRACTION

Parameter	Data
Process description:	A method to process pickled domestic lambskins into all-white tanned reverse or sueded non-slip shoe lining leather is given as follows. Material : Pickled domestic sheepskins : 25 lb per doz , selected for clean flesh and a minimum of slaughter cuts - pack of 50 doz - 1250 lb formula weight. Processing equipment: Drums : - 8 ft diam, 5 ft wide, 1 7 to 18 rpm . Flesh: Skins are drummed in brine to open up well. Flesh to clean off backs. Degrease : Standard drum degreasing with Stoddards Solvent. White pickle: Skins out of the degreasing run are left in a float of brine, about 7° Baume', at 90°F. Through the drum door on top of the skins add: (1) alum : - 3.0 percent - 37 .5 lb , and (2) Arkotan WHT* : - 3.0 percent - 37 .5 lb. Drum 30 min. White tan : On top of the skins in the white pickle add: (1) borax : - 25.0 percent - 312.5 lb - dry through the door. Put on the tight door and start the drum. Through the drum feed box add formaldehyde : - 10.0 percent - 125 lb - undiluted. Drum for 2 hours or until the float temperature is 100° - 105°F. Basify : Sodium bicarbonate : - 0.50 percent - 6.25 lb - dissolved in 20 .0 percent water - 250 lb - 30 gal - 90°F - add in 1 feed - drum in 30 min. Leather pH is 7 .1 ; shrinkage temperature , T., is 190°F. Neutralize and fat liquor : Cover with cold water. Drum 5 min with tight door on. Change to wash door. Wash out of formaldehyde tan - cold - 5 min; at 100°F - 5 min. Slat off to a low float. Through the drum door add : - (1) alum, dry, - 6.0 percent - 75 lb ; and (2) Arko Leather Oil C* : - 1.0 percent - 12.5 lb . Drum in 30 min. Leather pH is 4.5 to 5.0. Dump - Horse Up - Drain 24 hr - Flesh clean for sueded linings effect. Retan, whiten, fatliquor : Fleshed white skins are thrown into a clean white leather drum. Cover with cold water. Wash: 5 min - cold; 5 min - 100°F. Slat skins down to a low float. Add through the door on top of the skins : (1) alum, dry : - 3.0 percent - 37.5 lb; (2) Arko Leather Oil C* : - as is, 4.0 percent - 50 lb; (3) Arko Fatliquor MCA* : - as is , 2.0 percent - 25 lb; (4) Arko Colloidal White* : - as is, 2.0 percent - 25 lb ; and (5) Titanox OR 150, dry: - 1.0 percent - 12.5 lb. Put on tight door. Drum in 30 min. Neutralize: Borax, dry : - 2.0 percent - 25 lb - add through door - drum in 30 min. Leather pH is 4.3; T, is 190°F. Dump - Horse up overnight - Put out - Paste to dry in moderate heat - Damp - Samm - Stake as required for buffing - Buff for sueded reverse linings - Measure - Brush. Notes: Arkansas Co., Inc . white leather process materials Arkotan WHT; Arko Leather Oil C; and Arko Colloidal White are described in Alum-Formaldehyde Tannage IV of this series. Arko Fatliquor MCA is a nonionic emulsified mixture of neatsfoot and coconut oils ; pH in solution is 5 .5 to 6.0.

HERO ID:	6023394
Conditions of Use:	manufacture

EXTRACTION	
Parameter	Data
Production, import, or use volume:	In 1975, formaldehyde production capacity exceeded seven and one half billion pounds per year. Total production capacity was 7,643 MM lbs/yr, with 5,914 MM lbs/yr via silver process and 1,729 MM lbs/yr via metal oxide process.
Process description:	Formaldehyde is produced principally from methanol. Two processes are dominant in the U. S. today, the mixed oxide catalyzed process and the silver crystal (or gauze) catalyzed process. In 1975, an estimated 77% of U.S. formaldehyde capacity is based on the silver catalyst process. It was predicted that the total formaldehyde production using silver catalyst process would increase to 1.2×10^{10} lbs/year in 1985. Description for the silver catalyst process is provided. Prior to its admixture with methanol vapors, air is caustic washed to remove CO ₂ and trace sulfur compounds - the latter of which will poison the silver catalyst. The air is then heated to about 150 deg F. Fresh methanol and recycle methanol are combined, vaporized and then superheated to approximately 170 deg F. Heat is supplied by either exchange with the converter effluent or medium pressure steam. The heated air and superheated methanol vapors are combined in such proportions that the oxygen/methanol mole ratio is about 1:4. Decreasing the percentage of methanol in the mixture decreases conversion while increasing yield. The air-methanol mixture is induced into a battery - sometimes about three of catalytic converters. Upon passing through the silver catalyst, the net exotherm generated heats the vapors to about 1175 deg F. This temperature is maintained either by varying the air/methanol ratio or by means of combination heating and cooling coils located within the converters. The hot effluent gases must be quenched to avoid decomposing the formaldehyde. This is generally accomplished solely within the primary absorber, which is close-coupled with the converters, but feed vs effluent heat exchange is utilized - in part - by some plants. The primary absorber is a packed tower. The primary absorption liquid and quench - for the formaldehyde and unreacted methanol vapors is the so-called "F-M Liquor". This liquor is an aqueous solution containing about 28 to 30 percent formaldehyde and 20 to 22 percent methanol. Part of the FM liquor is withdrawn from the bottom of the primary absorber, pumped through a water cooled exchanger, and recirculated to the top of the primary absorber. The remainder of the FM liquor is withdrawn from the bottom of the absorber and pumped to intermediate storage. Uncondensed vapors and non-condensibles are withdrawn from the top of the primary absorber and 'blown' into the secondary absorber. The secondary absorber recovers the major portion of the uncondensed vapor by providing the necessary contact between the vapors and cool distilled water, which is introduced onto the top tray of the secondary absorber. The top of the tower is maintained at about 75 to 80 deg F by providing additional cooling via secondary coolers for the upper tray section. This minimizes hydrocarbon loss via the relatively large noncondensable overhead vent. The weak formaldehyde/methanol solution withdrawn from the bottom of the secondary absorber is pumped to the primary absorber and used as make-up. The FM liquor in the intermediate storage or surge tank is pumped to the product fractionator - a vacuum column. Here pure (99 + percent) methanol is taken as overhead product and recycled to either methanol storage or to the vaporizer. The bottom product is a nominal 37 wt. % solution of formaldehyde, containing less than 1% methanol. This solution may be treated for removal of trace amounts of formic acid prior to storage. Polymer formation and precipitation in storage is prevented either by the addition of supplemental methanol, by providing heated storage, or by both.
Number of sites:	Production via the silver process is distributed among over thirty different plants, ranging in size from 25 to 1300 MM pounds per year.

EXTRACTION	
Parameter	Data
Production, import, or use volume:	In 1975, formaldehyde production capacity exceeds seven and one half billion pounds per year. In 1975, total process capacity via silver process was 5,914 MM lbs/year and via metal oxide process was 1,729 MM lbs/year.
Process description:	Formaldehyde is produced principally from methanol. Two processes are dominant in the U. S. today, the mixed oxide catalyzed process and the silver crystal (or gauze) catalyzed process. In 1975, an estimated 23% of U. S. formaldehyde capacity is based on the mixed oxide catalyst process. It was projected that the total formaldehyde production capacity using this process will expand to 3.5×10^9 lbs/year in 1985 from 1.73×10^9 lbs/year in 1975. In the mixed oxide catalyzed process, methanol is mixed with a combination of air and recycle vent gas and then heated to between 220 and 350 deg F in a steam jacketed vaporizer. The air/recycle gas mixture will normally contain about 10% (vol.) oxygen, but always less than 10.9%. The methanol will normally comprise about 9.5% (vol.) of the total converter feed, although it is limited to about 7% for non-recycle operations. The super-heated vapors from the vaporizer pass into the converter, where the oxidation reaction takes place, in a multiplicity of tubes filled with a mixed oxide catalyst, between 650 and 800 deg F. The heat of reaction is removed by the circulating Dowtherm fluid surrounding the catalyst tubes and is used to produce steam. The converter effluent gases are cooled from approximately 500 deg F to about 220 deg F in a heat exchanger prior to being quenched to near 100 deg F in the absorber. The absorber consists of a bubble cap column which may have two water-cooled heat exchangers in the upper portion. The converter effluent vapors are introduced into the bottom section of the column and flow counter-current to the dilution/scrubbing water, which is pumped onto the top tray and flows downward through the tower. The formaldehyde vapors are absorbed by the water, forming a 37 to 53% solution. This exits from the bottom of the tower. The non-condensibles are vented from the top of the absorber where part is recycled and part goes directly to the atmosphere.
Throughput:	In 1975, approximately two thirds of the production was utilized in the formulation of various synthetic resins.
Number of sites:	In 1975, number of plants using silver process was 35 and using metal oxide process was 19. The primary licensors of the mixed oxide process are Reichhold and Lummus.
Chemical concentration:	Formaldehyde is normally marketed in aqueous solutions containing from 36 to 50 weight percent formaldehyde. The standard (USP) solution is 37 percent, although large scale industrial users prefer a nominal 50 percent solution. Formaldehyde solutions usually contain sufficient methanol to prevent precipitation of polymer during storage and shipping, although precipitation may be prevented in solutions containing relatively small amounts of methanol by keeping the solution warm.

HERO ID:	3970662			
Conditions of Use:	Incorporated into an article: Source of formaldehyde was unknown, but the raw material is uncured fibrous glass wool impregnated with phenol-formaldehyde resin.			
EXTRACTION				
Parameter	Data			
Process description:	In the forming area at the beginning of the fibrous glass headliner production line, uncured fibrous glass is fed from 35-pound rolls into a hot forming press (mold), where the binder system is cured. Formed headliners are cut into individual sections by a guillotine cutter as they exit the forming press. In the pretrim area, individual sections are trimmed by a pretrim press. In the marriage area, sheets of fabric and polyethylene are cut with a hot wire, then bonded to pretrimmed headliners by another hot press. In thefinal trim area, water jet guns automatically cut and trim headliners. Finally, in the packing area, headliners are hand finished with a hot glue gun. Headliners are transferred by hand from each area to the next. Fibrous glass dust is generated in the forming press and wherever fibrous glass is cut or trimmed. Plant 1 has five fibrous glass headliner production lines and plant 2 has three.In plant 2, non-fibrous glass headliners are manufactured by cold lamination processes. Adhesives are used to bond paper to foam core, or fabric to cardboard core. Cores are then cold rolled, stacked to air dry, and die cut.

Study Citation:	Hollett, B. (1983). Walk-through survey report: Control technology for adhesives at National Veneer Plant, Broyhill Furniture Industries, Inc., Lenoir, North Carolina.
HERO ID:	6558529
Conditions of Use:	Processing: Wood Product Manufacturing

EXTRACTION	
Parameter	Data
Process description:	The majority of the plys are alternate layers of gum and poplar with a maximum thickness of 1/8 inch. The resin used is Borden CR5H which is specified to contain no more than 5 percent free formaldehyde. The parts are layered in forms under approximately 200 psi applied pressure. The RF power is generated for a variable period, determined by the amount of glue line, ranging from 2 to 4 minutes followed by a cool-down/glue setting period of 1 to 2 minutes. The duties of the press crew are mixing, spreading, laying-up panels, loading, unloading, and separating. There is one glue mixer and one spreader operator who feeds the stock through the spreader. Two workers remove the glued layers and lay them in stacks according to the thickness desired. The same workers -then roll the stacks of panel stock on roller conveyors to the press input side. They load a prescribed number of layered panels in each form in the press. After the press has completed the heating and cool-down cycle, the unloading worker removes the hot panels. He places the stack on edge on the floor and leans over it, separating and checking each panel.
Throughput:	They produce about 1,500 square feet of panel per day per press (3 total presses). The production is divided about 40 percent, 13-ply and an equal percentage of 7-ply, with the remaining 20 percent ranging from 5- to 13-ply. There is one glue mixer and one spreader operator who feeds the stock through the spreader. Two workers remove the glued layers and lay them in stacks according to the thickness desired. The same workers -then roll the stacks of panel stock on roller conveyors to the press input side. They load a prescribed number of layered panels in each form in the press. After the press has completed the heating and cool-down cycle, the unloading worker removes the hot panels. He places the stack on edge on the floor and leans over it, separating and checking each panel. // During the day of sampling, Press No.1 processed 416 pieces of 9-ply, which equaled 1,433 square feet of plywood with 11,464 square feet of glue line. Press No.3 processed 375 pieces of 10-ply, which equaled 1,301 square feet of plywood with 11,709 square feet of glue line. A total of 881 pounds of glue was used that day.
Chemical concentration:	The resin used is Borden CR5H which is specified to contain no more than 5 percent free formaldehyde.

EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability		Metric 1: Methodology	High	The assessment or report uses high quality data and/or techniques or sound methods that are from frequently used sources (e.g., European Union or OECD reports, NIOSH HHEs, journal articles, Kirk-Othmer) and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness		Metric 2: Geographic Scope	High	The data are from the United States and are representative of the industry being evaluated.
		Metric 3: Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.
		Metric 4: Temporal Representativeness	Low	The report is more than 20 years old. The report captures operations, equipment, and worker activities that are expected to be outdated.
		Metric 5: Sample Size	N/A	No sample data.
Domain 3: Accessibility/ Clarity		Metric 6: Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions.

Study Citation:	Hovding, G. (1959). Free formaldehyde in textiles. A cause of contact eczema. Acta Dermato-Venereologica 39:357-368.		
HERO ID:	6117720		
Conditions of Use:	Textiles		
EXTRACTION			
Parameter	Data		
Process description:	Formaldehyde is used in the textile industry to improve the crease- and shrink-properties of cellulose fibers (rayon and cotton). It is used either alone, together with other reagents or in the form of simple formaldehyde derivatives. The process of formaldehyde resin treatment of textiles is as follows: (1) Impregnation of the textiles in a bath consisting of a catalyst and a pre-condensate and where the molecules are small enough to penetrate into the textile fiber; (2) Drying; (3) Condensation at a high temperature; (4) Washing to remove substances which have not reacted during the condensation process; (5) Drying.		
Chemical concentration:	Free formaldehyde in formaldehyde-treated fabrics should not exceed 50 ppm (0.005%). Samples of 256 different crease-resistance rayon and cotton textiles were examined for formaldehyde content. In 29 of the samples, no formaldehyde was detected (neither free nor combined). Out of the remaining 227 samples, 200 contained free formaldehyde and total formaldehyde in varying amounts. In 20 samples, only combined formaldehyde was found, and in remaining 7 samples traces of formaldehyde were found both in the free and the combined form. Only 7 samples contained less than 500 ppm. The majority of the samples, 132, show a content of free formaldehyde between 0.5-1.2 % . A single sample contains between 1.7 and 1.8 %. The majority of the samples, 150, contain between 3% and 7% of total formaldehyde. It is seen that rayon samples generally have a much higher content of free formaldehyde than the cotton samples. Majority of the rayon samples contain between 5000 and 12000 ppm of formaldehyde.

Study Citation:	Hovding, G. (1961). Contact eczema due to formaldehyde in resin finished textiles. Acta Dermato-Venereologica 41:194-200.			
HERO ID:	6117731			
Conditions of Use:	Processing: Finishing agents in textiles			
EXTRACTION				
Parameter	Data			
Process description:	”The usual principle for resin treatment is impregnation of the textile in a bath consisting of a resin pre-condensate and a catalyst, drying, curing at a high temperature, and washing to remove the catalyst and uncondensed resin which has not reacted during curing. The result of this process is the formation within the textile fiber of a thermosetting resin, which makes the fiber crease resistant, and in addition gives it other valuable properties such as decreased shrinking, easier drying, increased color fastness, improved draping and handling properties etc.” (1/7)			
Chemical concentration:	In unwashed samples the total formaldehyde showed approximate values between 4000 and 7000 ppm of fabric. Also, in sampled rayon, most samples contained 0.5-1.2% free formaldehyde. (2/7)

EXTRACTION				
Parameter	Data			
Process description:	The laboratory consists of two primary work areas, the black and white and the color film developing room (Room A) and the black and white print room (Room B). No color printing is done in this laboratory. Three full and three part-time employees work in these areas; employees can spend an average of 4 to 6 hours processing film. The majority of that time is spent in black and white developing and printing. In Room B the processing is done automatically with the Luth Mini 500. The processing chemicals are added manually and include Kodak Developer 55, and Kodak Rapid Fixer A and B. The Luth Mini operates at a temperature between 1100 and 120°F and exhausts directly into the work area. The spent chemicals are discharged through a hose into an open sink for disposal.

Parameter	Data			
Life cycle description:	In 1978, formaldehyde production was 60% used for plastics and resin production and 22% for production of intermediates. Resins (in order of consumption of formaldehyde): urea-formaldehyde, phenolic resins, polyacetal resins, and melamine resins. Chemical intermediates of formaldehyde are acetylenic chemicals, pentaerythritol, hexamethylenetetramine and urea-formaldehyde concentrates, diphenylmethanediamine (4,4'-methylene dianiline), 4,4'-methylenediphenyl diisocyanate, chelating agents, trimethylolpropane. Urea formaldehyde resin (25% of PV) is then used as an adhesive for composite wood products, compound for moulding, paper treating and coating, textile treating, surface coating, and foams for insulation. Phenolic resins (20-25% of PV) then used for adhesive in plywood, binder in fibreglass insulation, moulding compounds, foundry resins, laminates, wood, abrasives, and ion exchange. Polyacetal resins are used in unreinforced thermoplastic resins and melamine resins used in surface coating, moulding compounds, laminates, paper, textile treating and coating. "Among the chelating agents produced from formaldehyde, trisodium nitriloacetate is believed to be the most important. The principal use for trimethylolpropane is as an intermediate in the manufacture of polyols (both polyester and polyether types), used to make polyurethane resins"			
Process description:	"Production of acetylenic chemicals from formaldehyde, which represented 5-10% of US consumption in 1978, is based principally on the reaction of two molecules of formaldehyde with acetylene to produce 2-butyne-1,4-diol, which is then hydrogenated to 1,4-butanediol. This diol is the basis of tetrahydrofuran (a widely used resin solvent, reaction medium and intermediate in the manufacture of SpandexR fibres and poly-urethane elastomers), polybutylene terephthalate resins, polyurethanes [see IARC, 1979b], and a.-butyrolactone, an intermediate in the production of a family of 2-pyrrolidone derivatives, including N-vinylpyrrolidone and its polymer [see IARC, 1979c]. Pentaerythritol, made by the alkaline condensation of formaldehyde with acetaldehyde, is an important polyol used principally in the manufacture of alkyd resins. It is also involved in the production of synthetic lubricants, rosin and tall-oil esters, and of pentaerythritol tetranitrate which is used as an explosive and as a vasodilator. Hexamethylenetetramine, the condensation product of formaldehyde and ammonia, is used principally in the manufacture of curing agents for phenolic thermosetting resins. Urea-formaldehyde concentrates are used mainly to produce slow-release nitrogen fertilizers, commonly called 'ureaforms'"

Study Citation:	ICFI, (1985). Production and use of formaldehyde containing resins and options for controlling formaldehyde release from durable-press fabrics.			
HERO ID:	5901058			
Conditions of Use:	commercial use			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Of the approximately 5,700 million pounds of formaldehyde consumed in 1981, about 1.6 percent was used by the textile industry - mainly in the form of resins, which are used to impart durable-press properties to fabrics. In 1986, approximately 90 percent of the durable-press resin market was accounted for by one resin, dimethyloldihydroxyethyleneurea (DKDHEU) and its alkylated derivatives.			
Process description:	Wrinkle resistance imparted to fabric by the finishing agents is due to the cross linking of the resin with the fibers of the fabric. When the resin and fibers crosslink they hold the fabric in a rigid conformation. The greater the degree of crosslinking the better the durable-press properties. There are two major processes for the production of durable-press (DP) fabrics using formaldehyde or formaldehyde-derived resins . These are the pre-cure and post-cure processes. In the pre-cure process, final cure resulting in DP properties occurs at the mill, whereas in the post-cure process this final cure occurs after the fabric has been formed into a garment. The pre-cure process can be divided into four steps – fabric preparation, resin impregnation, drying, and curing.

HERO ID:	5901065				
Conditions of Use:	Manufacturing				
EXTRACTION					
Parameter	Data				
Production, import, or use volume:	Production of formaldehyde in 1983 was 5,398,012,000 lbs. Imports of formaldehyde in 1983 was 16,167,000 lbs and export was 17,174,000 lbs. Two highest formaldehyde use in 1978 was production of amino resins (includes urea and melamine) (29%) and production of phenolic resins (25%).				
Process description:	Formaldehyde is manufactured from methanol. There are two processes in commercial use at this time. The first and older of these utilizes a metal catalyst (usually silver) to form product formaldehyde from methanol, air , and steam. In this process a feed mixture of heated methanol, air, and steam is passed into the catalyst bed . The products are then passed into a condenser and through a countercurrent absorber . The top stream from the absorber is product formaldehyde while the bottom stream is distilled for methanol recovery and recycle. The second and newer process uses a metal oxide catalyst. In this process, air and vaporized methanol are passed through iron oxide-molybdenum oxide-filled tubes in a heat exchanger reactor. The product is cooled and passed to an absorber where the formaldehyde concentration of the resulting solution is controlled by the addition of water.				
Throughput:	In 1983, only about 63% of domestic capacity was utilized . See table 2				
Number of sites:	In 1984, there were 13 producers of formaldehyde. See table 1

Conditions of Use:	Processing as a reactant			
EXTRACTION				
Parameter	Data			
Life cycle description:	Formaldehyde finds many varieties of usage due to its high reactivity, colorless nature stability, purity in commercial form, and low cost. It serves as a resinifier curing agent, synthetic agent, disinfectant, fungicide, and preservative. Formaldehyde and phenol are also key raw materials in the industrial manufacturing of resins.			
Process description:	Figure 1 provides a schematic flow chart of the EOA process. Centrifugal extractors 1-6 rotated at about 3000 rev/min. The capacity of the system increased (from 1 to 2 m3/h) with the increasing rotating speed of the extractors. The detailed construction of the extractors and the extraction process equilibrium conditions were illustrated in our previous work. The main principle of EOA is illustrated in Figure 2. Step 1 was an extraction process, and step 2 was a reverse extraction with chemical reaction (reaction 1), by which extractant was recycled in the system. The DBD system for PFW shown in Figure 3 was set up in the mid-1990s, including an anaerobic reactor with a volume of 64 m3, an aerobic reactor of 22 m3, and a disinfection reactor of 2.2 m3. Although the system was running stably, long hydraulic retention time (HRT) and additional diluted water supply to keep a stable, low concentration of phenol and formaldehyde resulted in low efficiency and waste of resources.			
Throughput:	Study carried out in a factory with discharge capacity of 24 m^3 PFW (phenol and formaldehyde wastewater)/day, containing 1200 mg/L of formaldehyde.			
Chemical concentration:	Table 1 provides concentration of main pollutants (mg/L): original PFW - formaldehyde: 1200; one-stage extraction - formaldehyde: 965; two-stage extraction - formaldehyde: 860; three-stage extraction - formaldehyde: 620			
Comments:	Reactions 2 through 11 show the oxidation reactions.

EXTRACTION				
Parameter	Data			
Life cycle description:	Site manufactures formaldehyde then resinox*, a family of formaldehyde-phenol resin products available as liquid resins, laminating varnishes, and solid or lump resins processed into powdered resin compounds.			
Process description:	The unit processes and operations for producing the solid and liquid resins start out similarly, with the components being charged into the reactors according to the formulation required to meet the customers specifications. The list of component substances includes phenol, formalin, sodium hydroxide, concentrated sulfuric acid, hexamethylenetetramine, methanol, ethanol and xylene. Not all these substances are present in each product. for example HMT is a curing agent added only to the solid resin batches. The principal liquid ingredients are piped form storage tanks outside the building into weigh-cases for proportioning, then siphoned into the reactors.When fully reacted, the material destined to become solid resin may either be dumped directly onto the ”cooling floor” below the reactor or transferred to a holding tank for deposition onto a cooling belt. The hardened resin may be milled, blended , and screened before bagging. the liquid resins are transferred to holding tanks, then passed through filters before being placed in refrigerated tank cars or trucks is recommended to prevent hardening of the liquid resin.

Life cycle description:	The plant develops and produces highperformance special purpose battery systems,especially for military or aerospace applications.Products manufactured at the plant includethermal batteries, lithium-metal sulfide batteries,sodium-sulfur batteries, lead fluoroboric batteries,nickel-iron batteries, electroexplosive devices(e.g., squibs, wire cutters, matches, etc.), andmechanical actuators.			
Process description:	Powder for the pills is mixed in the process room. The pill room, located in building 108, houseseight large hydraulic presses (six 175-ton presses,one 350-ton press, and one 410-ton press) thatproduce battery pills. Batteries are assembled by hand in dry room 108.Utility battery builders stack and wrap batterycomponents. These are loaded in casings by abattery loader. Welders seal the casings. Someparts fabrication, such as Fiberfrax cutting, takesplace in dry room 108 as well. In the potting area for thermal battery production,potting compounds are mixed in hoods and heatedbefore use to make them pourable. The mixedpotting compounds are poured over parts (batteryheaders) held in jigs on tables in the work area.Ovens are used to cure the potting compounds. Contacts are soldered on batteries using solderingirons, 70/30 tin lead solder, a rosin flux, and smallamounts of isopropanol. The mercury treatment processconsists of dipping negative battery plates into amercuric chloride solution. After dipping, theplates are soaked and rinsed, and thesoaking/rinsing cycle is dependent on the type ofbattery being built. Finally, the plates are dried inan oven. The oven operator wears an airpurifyingrespirator with mercury canisters.

EXTRACTION				
Parameter	Data			
Process description:	Urea–melamine–formaldehyde (UMF) resin was used to manufacture HDF. The molar ratios of the resin was 0.95 (F/M + U). Before the HDF was manufactured, 3 parts (to resin) of 25% ammonium chloride as a hardener and 13 parts of 44% wax solution for water-proofing were added. The wood fiber distributed from Dongwha Enterprise was made from Korean pine (P. densiflora) with amoisture content of 4%. TheMDFwas manufactured using the above adhesives, in order to have a specific gravity of 0.8. The mixture was then hot pressed, to form composite boards, at a peak pressure of 40 kgf/cm2 and a temperature of 180 °C. The main pressing time was 4min and the pressure was then released in two steps of 1min each. Overlay paper, deco paper and valance paper were impregnated with melamine-papers pressed at about 200 °C and called low pressure melamine (LPM) as shown in Fig. 1a. The resin for impregnation is shown in Table 1. Finally, the edges of the product aremachined to produce a tongue and groove profile. In the case of engineered flooring, 0.5 mm-thick fancy veneer of maple is glued to a 7.2 mm-thick plywood sheet and pressed at about 160 °C.

EXTRACTION				
Parameter	Data			
Process description:	In the autopsy suite, official autopsies were conducted for deaths from homicide, suicide, fires/ burns, certain accidents, and other suspicious or unusual deaths. During a typical autopsy, a pathologist and forensic assistant opened the decedent’s chest cavity to remove and examine the internal organs. Organ tissue samples were removed and placed in open containers of a formalin solution. This solution was used to fix and preserve the tissue specimens for histologic examination. To gain access to the brain tissue, the skull cap of the decedent was removed with a hand-held oscillating Clean Cut Autopsy Saw system, model 04-NS3 (Leica Microsystems, Buffalo Grove, Illinois [formerly Surgipath Medical Industries, Richmond, Illinois]). Tissues collected during autopsies were fixed, processed, embedded in paraffin wax, sectioned, mounted on a slide, and stained for microscopic examination of the tissue cells in the histology laboratory. Following autopsies, these tissues were delivered to the laboratory in containers of 100–300 milliliters of formalin solution. The tissues, contained in small cassettes, were removed from the containers and loaded into a tray for further processing. Typically, this work was done near a hood on the wall directly above the sink into which the formalin waste was poured after the cassettes were removed. Processing of the tissues sequentially removed the tissue fluids and replaced them with alcohol and paraffin so that the tissue was fixed in a block of paraffin. Chemicals used in the tissue processing included dehydrants such as ethyl, isopropyl, and methyl alcohol, and aliphatic hydrocarbons. The total time for loading tissue cassettes and tissue processing was 1–1.5 hours; this occurred once every other week at a minimum to twice a week at a maximum. After processing, the block was sliced, and the tissue specimens were mounted on a slide, stained, and viewed under a microscope

Parameter	Data			
Process description:	An application of wax is sprayed by the auto wax unit into the back, or open end of the composite can. This is done so that when Kardon Industry customers insert a closing device after the composite can is filled at their facility, air and moisture penetration is reduced. The composite cans are automatically fed from the production lines to the auto wax operation. Two duplex spray heads operate simultaneously, spraying wax into the open end of the composite cans. During our first visit, the wax was preheated with mineral oil in a drum and then hand carried in open buckets to two melt tanks (reservoir) on the auto wax machine. This process was modified before our second visit so that the wax was automatically pumped directly from the heated 55 gallon drum to the reservoir. This eliminated the need to hand transfer the wax from the drum to the reservoir.

Conditions of Use: Plastic Material and Resin Manufacturing; Plastic Product Manufacturing	
EXTRACTION	
Parameter	Data
Process description:	Plastic containers are manufactured from polyethylene. Two molding processes are used to make the containers from the raw plastic pellets. Injection molding is used to make most of the containers that require covers, while blow molding is used to make containers with special shapes and specifications. Several container molding machines, including machines that mold the covers, are located throughout the facility. Before molding, the plastic pellets are melted and color dyes can be added. The molded containers are processed by trimming, shrinking, or attaching handles. Many of the containers also require silk screening to apply customer logos and special labels. The silk screening operations are performed on a manually operated machine or an automatic (offset) machine. Similar silk screening inks are used in both areas. For containers being silkscreened by the offset machine, handles are attached after the logos are allowed to dry. The finished plastic containers are inspected and prepared for shipment.

EXTRACTION

Parameter	Data
Life cycle description:	Processing
Process description:	After being molded, the fascia are placed on a robotic paint line. The robotic paint line sprays the parts with three different coats. The first coat applied is an adhesive promoter, which increases the surface area on the part to promote adhesion of the subsequent coats. The second coat is the base coat which provides the coloring to the fascia. The paint line can apply one of 26 different colors which are all mixed in the paint kitchen. The third coat is a clear coating that provides the finish to the parts. After the bumpers are painted, they are cured in an oven, allowed to cool, and then prepared for shipment to an automotive assembly facility. The paint kitchen is a separate rectangular building attached to the main facility where the various coatings are stored, prepared, and distributed to the robotic paint line. All the coating materials are pneumatically conveyed and continuously recycled to the robotic paint line through carrier lines from pneumatic mixing totes located in the paint kitchen. The paint kitchen is physically separated by walls and automatic fire doors into three areas: storage, preparation, and distribution. The largest of these three areas is the storage area. Many of the various coatings and numerous solvents for the coatings are shipped in 55 gallon drums and are stored in this area. The second or middle area is the preparation area where drums of the various coatings and solvents are kept for easy access. Many of these drums are tapped, electrically grounded, and kept on horizontal racks. The third area is the distribution area which houses all of the pneumatic mixing totes and components of the recirculation system. All the coating carrier lines are connected to the main facility in this area. There are approximately 26 pneumatic mixing totes for the various colored base coats, adhesive promoter, and finishing clear coat.
Throughput:	During full production, the plant capacity is 3,000 fascia (painted parts) per day. The fascia are manufactured in one of four injection molding machines (300 ton presses) that can produce parts at the rate of 45 parts per hour each for a total facility capability of 180 parts per hour. Each of the parts weigh approximately ten pounds.

Production, import, or use volume:	no information provided			
Process description:	Boise Cascade operated two production lines, built in 1966 and 1971, respectively. The process is fairly standard for the era; that is, a storage area, followed by a milling and drying department, followed by a production building that contains two Bison forming stations, two Washington Iron Works prepresses, and two 14-opening Washington Iron Works hot presses. Both lines have a fiberglass reinforced plastic caul that carries the loosely formed mat through the prepress and then is stripped away and sent back under the forming line to receive a new mat. Both lines are operationally independent from each other. Production in 1992 was 185 M ft2 (3/4 in. basis), or 327,000 m3. In the mid-1970s the product mix on the 4 by 24 ft line was heavy to underlayment because that was what the line was designed to build. The five foot wide panels were almost exclusively cut to industrial sizes. Dependence on underlayment was reduced and by 1992 none have been made. As early as 1975, Boise Cascade reviewed emission reduction, working principally with the former Chembond, Inc. (now Neste), because they offered low fuming resins. Boise Cascade added a liquid urea scavenger in 1982 to the face and core of the low fuming resins. By 1983 board emissions were averaging below 0.2 ppm with the combination of low mole ratio resins and liquid urea scavenger. By the use of new resin technology, formaldehyde scavengers, substitution of small amounts of other resins, and combi resins, it has been possible for the Boise Cascade plant to meet the ever decreasing emission standards.

EXTRACTION				
Parameter	Data			
Process description:	The furnaces consists of a cylindrical metal shell, lined with refractory brick; a crucible, cup-shaped container that holds the metal is placed in the furnace. The refractory crucible containing the molten metal is lifted from the furnace by an overhead crane and positioned in a bruggy ladle, which is supported on a wheeled carriage, and transported to pouring area. The ladles are managed by a crane, and a geared mechanism tilts them for pouring. The metal is poured into sand molds on an open pouring floor. Fluxes composed of chlorides or fluorides of the alkaline earth metals are used to flux the molten magnesium and aluminum alloys, respectively. In addition to the fluxing procedure, the aluminum alloys are de-gassed by the addition of hexachloroethane tablets to the molten metal. When the molten metal in a mold has solidified, the casing is separated from the mold, and the core is removed from the casting in an operation known as knockout. An automated or manual abrasive blasting process is used for mold and core separation. The automated process, termed "new knockout", involves a rotary table bleating machine. The sand mold is placed on a table that carries it through a chamber where an air blast or centrifugal wheel projects a metallic abrasive against the mold with resultant removal of the sand. The manual process, termed "old knockout", involves the manual sand blasting of the casting by a worker.

Study Citation:	Kopf, P. W. (2003). Phenolic resins.
HERO ID:	6549167
Conditions of Use:	Processing-Incorporation into a formulation-Plastic material and resin manufacturing

EXTRACTION	
Parameter	Data
Production, import, or use volume:	In 2000, worldwide consumption of phenolic resins exceeded 4 106 t; slightly less than half of the total volume was produced in the United States (59). The largest-volume application is in plywood adhesives, an area that accounts for &49% of U.S. consumption (Table 8). All wood bonding applications accountfor about two-third of phenolic resin use. During the early 1980s, the volume of this application more than doubled as mills converted from urea–formaldehyde (UF) to phenol–formaldehyde adhesives because of the release of formaldehyde from UF products.
Process description:	Phenolic resins are prepared by the reaction of phenol or substituted phenol with an aldehyde, especially formaldehyde, in the presence of an acidic or basic catalyst.In one form or another, formaldehyde is used almost exclusively in the production of phenolic resins, regardless of the type of phenol (Table 3). It is frequently produced near the site of the resin plant by either of two common processes using methanol (qv) as the raw material. In the silver catalyst process, the reaction takes place at 600–6508C and produces water and hydrogen as by-products. The more common metal oxide process operates at 300–4008C. The gaseous formaldehyde is absorbed in water, and the final product is a formalin solution containing 36–50% formaldehyde. Of the various chemical forms of formaldehyde, the aqueous form is preferred for making phenolic resins, even though at least half of this form is water. The water serves to moderate the reaction and is readily removed in processing equipment.Hexa, a complex molecule with an adamantane-type structure, is prepared from formaldehyde and ammonia, and can be considered a latent source of formaldehyde. When used either as a catalyst or as a curative, hexa contributes formaldehyde-residue-type units as well as benzylamines.In the range of pH 4–7, formaldehyde substitution of the phenolic ring is possible, using divalent metal catalysts containing Zn, Mg, Mn, Cd, Co, Pb, Cu, and Ni; certain aluminum salts are also effective. Organic carboxylates are required as anions in order to obtain sufficient solubility of the catalyst in the reaction medium, as well as to provide a weak base. Alkaline catalysts are also effective in the polymerization–depolymerization of methylene glycol. The mechanism of the formaldehyde addition to the phenolate is still not completely understood. The most likely mechanism involves the contribution of phenol hemiformals.In a conventional novolak process, molten phenol is placed into the reactor, followed by a precise amount of acid catalyst. The formaldehyde solution is added at a temperature near 908C and a formaldehyde-tophenol molar ratio of 0.75:1 to 0.85:1. For safety reasons, slow continuous or stepwise addition of formaldehyde is preferred over adding the entire charge at once. Reaction enthalpy has been reported to be above 80 kJ/mol (19 kcal/mol) (30,31).The heat of reaction is removed by refluxing the water combined with the formaldehyde or by using a small amount of a volatile solvent such as toluene. Toluene and xylene are used for azeotropic distillation. Following decantation, the toluene or xylene is returned to the reactor.The process for high ortho novolaks is similar to the one used for those catalyzed by strong acid. Zinc acetate is used at concentrations higher than the acids, typically 2% or more. The formaldehyde/phenol ratio is similar (0.75–0.85) but yields are 5–10% lower than those produced with strong acids, and reaction times are longer. Problems with gel particles and bulk gelation occur more frequently because small amounts of reactedibenzyl ether groups are present. Overall, the process is more expensive because of higher raw material costs, lower yields, and longer cycle times.Like the novolak processes, a typical resol process consists of reaction, dehydration, and finishing. Phenol and formaldehyde solution are added all at once to the reactor at a molar ratio of formaldehyde to phenol of 1.2–3.0:1. Catalyst is added and the pH is checked and adjusted if necessary. The catalyst concentration can range from 1 to 5% for NaOH, 3 to 6% for Ba(OH)2, and 6 to 12% for hexa. A reaction temperature of 80–958C is used with vacuum-reflux control. The high concentration of water and lower enthalpy compared to novolaks allows better exotherm control. In the reaction phase, the temperature is held at 80–908C and vacuum-refluxing lasts from 1 to 3 h as determined in the development phase. Benzoxazine resins are prepared by the reaction of phenol, formaldehyde, and an amine. In one particular example abenzoxazine is prepared from bisphenol A, formaldehyde, and aniline to give 2,20-bis(3-phenyl-4-dihydro-1,3,2-benzoxazine) propane. When heated to about 2008C the methylene bond to oxygen breaks and reforms onto the available ortho positions of adjacent moieties to give dibenzylamine structures.
Number of sites:	U.S. phenolic resin manufacturers include Ashland, Borden Chemical, Cytec Fiberite, Durez, FiberCote Industries, H.B. Fuller, P.D. George, GeorgiaPacific, International Paper, Lockport Thermosets, Maruzen America, Plastics Engineering, Resinoid, Sumitomo America, TriQuest, and Vantico.

Conditions of Use:	Paper Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	Formaldehyde was the main component of several chemicals used in the paper and recycled-paper industry and the concentrations that exceeded the present TLV value were measured during the re-pulping of waste pulp. Microbes may cause problems because of the warm and wet conditions in many departments, and high concentrations of bacteria were measured, especially in the de-inking processes, in wastewater.			
Comments:	This article summarizes the results of 3,873 measurements carried out in the production departments of paper and paperboard mills and recycling plants in 12 countries.... a team of industrial hygienists has integrated the measurements in the database with mill-specific information from the questionnaires answered by the participating companies, to create a pulp and paper department-exposure matrix (PAPDEM) for 25 major exposure agents... A description of this matrix and a summary of exposure estimates have been published elsewhere (Kauppinen et al. 2002).

EXTRACTION				
Parameter	Data			
Process description:	"Formaldehyde is produced industrially by the catalytic oxidation of methanol (McKetta and Cunningham, 1985b). The more common catalysts are silver metal or a mixture of an iron oxide with molybdenum and vanadium. During the more commonly used FORMOX® process, methanol and oxygen react at ca 250-400 °C in the presence of iron oxide in combination with molybdenum and/or vanadium to produce formaldehyde, according to the chemical equation: 2 CH3OH + O2 -> 2H2CO + 2H2O (R9) Another possibility for formaldehyde production is the metal oxide process. The main differences compared to the silver process are: •working with excess air •type of catalyst •a lower temperature level The metal oxide process can be described as a two stage oxidation reaction during the vapourization phase, which involves an oxidised (Kox) and a reduced (Kredox) catalyst. Methanol (inlet stream M) is fed into the heated vaporiser (V; Fig. 7). The process gas, a mixture of fresh air (inlet stream air) from the atmosphere, is drawn through a filter and compressed in a blower (B). The methanol and air mixture are heated in a vaporiser (V) and pre-heater (H) before entering the reactor (R). The conversion of methanol to formaldehyde takes place in tubes filled with a metal oxide catalyst. The reaction’s heat is removed by using steam production or for electricity cogeneration. The reactive gases are cooled (C) and enter the absorption tower (A), where the absorption of the formaldehyde takes place by using 5478 kg/h (1.52 kg/s) fresh water. This fresh water would be replaced by using wastewater from the methanol process. (pg 5)"			
Chemical concentration:	sold as a 37% solution in water known by trade-names like formalin or formol (pg 5)

Parameter	Data			
Process description:	The facility receives pre-cured, finished fabric from a textile-finishing plant. The shirt fabric is treated with formaldehyde-based resins, which give the fabric crease-resistant characteristics (permanent press). The resin-treated fabric is cured before it is received. The first step in the shirt manufacturing process is cutting of shirt parts from the fabric (cutting area). Many layers of fabric must first be spread out on a long table. All of the layers are then cut simultaneously with hand-held saws (cutters) or with dies. When a hand-held cutter is used to perform this step, a pattern is first laid over the top layer and the operator cuts according to the pattern. Cutting operations were done during the first industrial hygiene survey at the time of the second survey cutting operations were discontinued. After the cutting operations, the shirt parts are assembled. Parts of the cuffs, collars, and fronts are assembled into complete pieces (small parts area), then the major pieces, such as yokes, sleeves, collars, cuffs, and fronts are assembled into complete shirts (assembly area). Most of the various assembly operations require sewing with sewing machines appropriately modified for each type of operation. Some assembly operations (collar and cuff making) make use of heat to form or fuse together (in conjunction with a heat-sensitive adhesive) Various parts (fusing area).The finished shirts are inspected (trim/inspection area and moved to the apparel pressing operations where conventional hand irons are used to press the shirts (Pressing area). The shirts are then folded (folding area) and packaged in bags and boxes for shipping (boxing area).Finished shirts that become soiled during manufacturing are taken to the cleaning area where the dirt/stains are treated manually with chlorinated dry-cleaning solvent.

Process description:	The main processes, common to all PrCBs, are drilling, image transfer, and electroplating. Holes are drilled into PrCBs to provide layer-to-layer interconnections on double-sided and multilayer circuits. These holes are subsequently “plated through” or made conductive by plating copper onto the hole barrels (the vertical, cylindrical surface of the hole). Because most rigid PrCB substrates consist of epoxy resin and glass, direct electroplating of hole barrels is not possible since this material will not conduct electricity. Therefore, a seed layer or coating of conductive material (usually electroless copper) must be deposited into the barrels of the holes before the electrolytic copper plating can occur. Chemical products utilized in the electroless copper process contain formaldehyde or dimethylformamide.

Study Citation:	Liu, M., Wang, Y., Wu, Y., He, Z., Wan, H. (2018). "Greener" adhesives composed of urea-formaldehyde resin and cottonseed meal for wood-based composites. Journal of Cleaner Production 187(Elsevier):361-371.
HERO ID:	5956691
Conditions of Use:	Processing (UF resin/adhesive)

EXTRACTION	
Parameter	Data
Production, import, or use volume:	The current global production of urea-formaldehyde (UF) resins exceeds 5 million metric tons annually.
Life cycle description:	UF resins are widely used in particleboard, medium density fiber board, and interior plywood manufacturing. The source of free formaldehyde from UF resins is believed mainly from un-reacted formaldehyde and the reversibility of amino-methylene link in the cured resin network. Life cycle assessment (LCA) analysis is an established method to study, to estimate, or to evaluate the possible impacts of manufacturing processes or products on the environment. To compare the "greenness" of normal UF resin and the adhesive composed of UF resin and cottonseed meal, the LCA analysis was conducted. The impact assessment was carried out using TRACI (v2.1, February 2014). In this analysis, the lifecycle impact of cotton production to this by-product and the impact to the LCA analysis of the adhesives composed of UF resin and cottonseed meal was not considered. Based on the LCA analysis, the replacement of cottonseed meal adhesive in a UF resin could make the adhesive manufacturing process "greener". In this point of view, adhesives composed of cottonseed meal and UF resin are "greener" adhesives compared to pure UF resins. But this LCA analysis was based on a very simple model. It was also simplified with many assumptions.
Process description:	The UF resin with a 1.45 formaldehyde to urea (F/U) molar ratio was prepared by following three steps of urea addition. First, paraformaldehyde was dissolved in distilled water at a basic condition (pH ¼ 8.0, adjusted by 8% NaOH). The formaldehyde solution was heated and maintained at 70 C. Then, the first (32.2% of total urea) and second part (31.3% of total urea) of urea were added with a 10 min interval into the formaldehyde solution for the methylation reaction to occur. Next, the reaction was followed by a poly-condensation or polymerization reaction under an acidic condition (pH ¼ 4.8, adjusted by 8% H2SO4) until the reactants reached a target viscosity of LMN. The solution pH value was adjusted to a basic condition (pH ¼ 8.0) followed by the addition of the third part of urea (36.5% of total urea). After cooled down naturally, the UF resin was obtained.
Comments:	Note: This is a new method to produce UF Resin using cottonseed meal which is supposed to be "greener"

Parameter		Data		
Life cycle description:		Chermical Substances in Metal products: Foundary		
Process description:		Copied from source: "The study was undertaken at a steel foundry that specialises in producing castings for heavy industry and rolling stock. Castings are produced by pouring molten metal into a mould cavity. The mould that is formed in a box determines the external shape of the casting. Cores are placed into the mould cavity anddetermine the internal shape of the casting. There are two separate major casting areas within the foundry. When a small number of castings is required these are produced in the general foundry by a jobbing mould method using the Furane process. For a large number of castings a semimechanised method uses a high pressure greensand moulding process (hereafter called the line). In both areascors of varying composition are placed in the mould cavities. Workers in the casting areas are exposed to fumes arising from the various core and mould materials after metals at high temperatures have been poured into the mould cavities. After the castings have cooled they are transferred to the aftercast section where they are subjected to various finishing procedures such as shot blasting,grinding, and cutting. Those working in the aftercast area were not exposed to any of the resin fumes or vapours found in the rest of the foundry. Nevertheless,they were clearly exposed to some fumes-for example, from welding-and to dusts from the finishing procedures. The aftercast section was the only area in the foundry that could provide sufficient workers with whom we could compare thoseexposed to resin fumes and vapours elsewhere. In a separate area cores are produced by several different processes, which include the following: Furane process-" Chemrez 204" (urea formaldehyde resin condensed with furfuryl alcohol) is mixed with phosphoric acid (as a catalyst) and sand. Isocure process-A complex polyurethane resin is formed by mixing methylene diphenyl di-isocyanate(MDI) dissolved in petroleum hydrocarbon solvents and phenol formaldehyde resin dissolved in petroleum solvents with dimethylethylamine (DMEA)as a catalyst. Shell process-Phenol formaldehyde resin is used with a catalyst, hexamethylenetetramine. Carbon dioxide process-Sodium silicate is mixedwith either various glycerol acetates or carbon dioxide gas under pressure.Oil sand process-" Maidex" (acid hydrolysed starch and drying oil) is mixed with sand. The cores are baked in an oven at between 350°C and 550°C for several hours."

EXTRACTION	
Parameter	Data
Production, import, or use volume:	Production figures of urea resins go from 190,000 metric tons in 1964 to 321,000 metric tons in 1970. Melamine resins ranged from 69,000 metric tons in 1964 up to 117,700 metric tons in 1970. Acetal resins had 20,000 metric tons in 1965 and 39,000 in 1970. Phenol formaldehyde had 263,400 metric tons in 1962 and 462,200 in 1970. Urea resin consumption in closeres was 6900, 6800 and 7900 for 1971, 1972 and 1973; Urea resin consumption in electrical devices was 11,400, 10,900 and 12,600 for 1971, 1972, and 1973. For 1971 through 1973 melamine resin consumption in buttons was 900, 800, and 900; for dinnerware it was 19,100, 18,200 and 19,100; for sanitaryware it was NA, 500, and 600; Bonding and adhesives resins for the years 1971 to 1973 for fibrous and granulated wood were 199,000, 232,000, and 262,000; for laminating 22,000, 24,000 and 24,000; for plywood 31,000, 40,000 and 40,000; for paper treating and coating 14,000, 16,000 and 22,000; for protective coating 19,000, 28,000 and 33,000; for textile coating and treating 23,000, 23,000 and 26,000; Consumption for acetal resins in metric tons for 1971 to 1973 were for appliances - 4,820, 5,600, and 5900; for consumer products - 3090, 3500, and 3800; for electrical/electronics - 1910, 2100, and 2500; for machinery parts - 2550, 2800, and 3900; for plumbing and hardware - 2550, 2800 and 4000; for sheet, rod, tube - 1320, 1500, and 1800; and for transportation - 6050, 5700, and 6500; consumption of phenol formaldehyde resins from 1971 to 1973 in metric tons: bonding and adhesive resins for coated and bonded abrasives - 8000, 9100, and 11,200; for fibrous and granulated wood - 30,000, 40,000 and 42,000; for friction materials - 14,000, 13,400, and 14,700; for foundry and shell moldings - 39,000, 43,600 and 50,000; for insulating materials - 88,000, 107,000 and 112,000; for laminating buildings - 31,500, 26,100, 26,200; for electrical/electronics - 7000, 7300, and 7300; for furniture - 12,000, 16,000, and 17,000; for plywood - 152,000, 163,000, and 125,000; for protective coatings - 10,000, 9600, and 10,100; molding compounds for appliances - 17,500, 31,800, 41,400; for business machines - 4400, 6100, and 6800; for closures - 9100, 4500, and 4100; for electrical controls and switches - 40,400, 56,000, and 61,000; for telephones - 9800, 9300, and 9500; for wiring devices - 15,600, 15,900, and 16,300; Housewares for utensils and handles - 11,200, 14,300, and 14,700; for machine parts - 4000, 4800, and 5100; for transportation - NA, 27,700 and 30,270
Life cycle description:	The versatile formaldehyde resins have usually wide application ranges. The amino resins are used in closures and wiring devices, large and small appliance housings, dinnerware, buttons, ash trays, and utensil handles. They are used as adhesives in plywood and in laminating. In textile treating, they are used for greasproofing, water repellantcy, and flame retardance. In paper treating, they are used for improving wet strength, rub resistance, and dry tensile values. The acetal homopolymer is used to replace metal parts in the plumbing industry. It is used in truck-trailer connectors and in such a variety of items as furniture casters, hardware items, bodies of lighters, replaceable cartridges in shavers, toy components, telephone pushbuttons, and stereo-tape and cassette components. The acetal copolymer is used in automotive gears and fuelemmission systems. It is also used to give satiny surfaces and hardness to pen barrels and other items where an attractive appearance is desired. Its dimension stability qualifies it for use in aerosol containers under continuous pressure. The phenolics are used as adhesives in the wood particle board used in building panels and furniture, and as a water-resistant glue for exterior grade plywood. They are used extensively as automotive components in transmissions, distributor caps, coil towers, rotors, fuse blocks, for brake linings, clutch parts, and transmission bands.

EVALUATION				
Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	Data is from a report by EPA so contains high quality data.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	Data is for US.
	Metric 3:	Applicability	High	Data is applicable to multiple COUs
	Metric 4:	Temporal Representativeness	Low	Data is over 20 years old.
	Metric 5:	Sample Size	Medium	Characterized by a range of data.

Parameter	Data			
Production, import, or use volume:	In 2004, U.S. production was 9,534,992,839 pounds and consumption was 9,507,960,000 pounds; TURA Data Formaldehyde 2009 Usage- Boremc Specialty Chemicals- 1, Dow- 5365, Ineos Melamines (claims trade secret), MW Custom Papers-44879, Raytor Compunds, Inc- 1001513, Suddekor LLC- 42400, The Dodge Company- 889402; TURA Data Formaldehyde 2009 Byproduct-Boremc Specialty Chemicals- 72905, Dow- 307347, Ineos Melamines (claims trade secret), MW Custom Papers-44879, Raytor Compunds, Inc- 1726, Suddekor LLC- 2290, The Dodge Company- 6161			
Life cycle description:	Formaldehyde is generally produced for local consumption, with world trade accounting for only two percent of production in 2003, as it is easy to make but costly to transport. Its primary use is to make urea-, phenol- and melamine-formaldehyde resins. Particle-board and plywood using urea- and phenol - formaldehyde resins account for more than one-third of demand.The majority of applications are in wood and construction-related industries as urea-formaldehyde, phenol-formaldehyde and melamine-formaldehyde glues, resins and stiffeners; followed by uses as a chemical intermediate (e.g. pentaerythritol, hexamethylenetetramine, butanediol) to manufacture another chemical of commerce. Some is used in specialty thermoplastic resins, in the textile/apparel industry as a whitener/finisher/stiffener for items of clothing and an additive for wrinkle-resistance and crispness of appearance, and for preservative additives in soaps, lotions, shampoo, etc.			
Number of sites:	Nineteen companies reporting during the nine years examined, only six were still reporting in 2009 (to TURA).

EXTRACTION				
Parameter	Data			
Process description:	The brake manufacturing process begins in the mixing room where large vats are filled with a metallic disk brake lining compound (brake dust) to create pad stock. The brake dust contains a blend of steel wool, resins, coke, rubber, colloids, barytes, synthetic graphite, magnesia, and fiberglass. After mixing, vats containing pad stock are transported via forklift trucks and conveyor transports to heat ejection integral molding (HEIM) machines located in departments 2 (rotary HEIMs) and 37 (square HEIMs). Pad stock is transferred into dies of HEIM machines where brake pads are formed by mechanical pressure, then initially cured attemperatures ranging from 290-455 degrees Fahrenheit (°F). Each HEIM machine is equipped with local exhaust ventilation exhausting to dust collector hoppers. After brake pads are formed and initially cured, they are deposited into unloader bins to cool and for temporary storage. Local exhaust ventilation is also provided at each unloader bin. Brake pads go through a grinding process and a final cure in department 40. The curing ovens indepartment 40 are located adjacent to department 2, and are served by a direct exhaust ventilation system.Insulator parts and brake shoes for brake pads are cut and formed by a steel press. Adhesive is applied to brake shoes with roll coating machines (department 40), and the brake shoes are attached to the brake pads. The brake pads are transported to paint lines in departments 2 and 12, where they undergo abrasive blasting (with glass beads) and an electrostatic application of epoxy powder paint. The pads enter a paint cure oven (380-420 °F), have an insulator applied, and are then transported to aninsulator cure oven to complete the paint line process. The assembly process (department 40) involves attaching wear sensors onto brake pads.Several other processes occur in the departments of concern. Dye wash areas are located in departments 2 and 37, where the molds used in the HEIM machines are cleaned in alkali baths equipped with local ventilation. Additionally, a cold-mold machine, also used to produce brake pads, is located in department 37 adjacent to department 2.

HERO ID:	3042078
Conditions of Use:	Use of Metalworking fluid

EXTRACTION

Parameter	Data
Process description:	The machining area of the Woodward Governor plant covers approximately 33,500 square feet and contains about 95 machines. Just prior to the NIOSH survey, Woodard had renovated the machining area and relocated machines within the space. Each machine is self-contained and does not share its metal working fluid (MWF) with any other machines through any kind of central system. None of the machines contain local exhaust ventilation (LEV), but many are partially or totally enclosed when operating. The majority of machines use water-based MWFs, either a Blasocut® water-soluble oil or a Syntilo® synthetic fluid, but a few use one of two of Hansterfer's Hard Cut® straight oils. None of the MWF suppliers has onsite personnel at this plant; the plant's maintenance department is responsible for all MWF maintenance. Each individual operator is responsible for adding new fluid (make-up fluid) as needed based on the automatically monitored fluid concentrations, and they can also request a complete change-over of fluid from the maintenance department. The maintenance department also performs scheduled fluid change-overs, which vary by machine and fluid type. The machines that use straight oils are only changed-over once a year or on request, during which time the machine is drained, rinsed out, wiped out, and refilled with new fluid. The filters on these machines are changed only as needed. The machines that use the water-based fluids are changed-over more frequently (depending on the machine, every one to several months), and this change-over involves pumping the fluid out of the machine, cleaning out the metal chips, rinsing, using a cleanser (Cimclean® 30) and brush, a final rinsing of the tanks and lines, wiping the inside and outside of the machine, and refilling it with new fluid. During this process the machine must be shut-down for two to eight hours (varies by size of the machine). The responsible maintenance person keeps the records of maintenance in his notebook and on updated stickers on each machine. The only machines without scheduled change-overs are the Hitachi and Citizen lathes; the fluids in these machines are only changed upon operator request because the operators do not want any scheduled shut-downs. A MWF recycling system was installed for the Blasocut® fluids. The fluids in the machines that use Blasocut® are scheduled to be recycled (emptied from the machine, recycled in the Blaser Swiss Lube filtration system, and returned to the machine) every three weeks by the night maintenance personnel. The total cleaning and change-over of fluids for these machines was anticipated to be every six months.

Conditions of Use:	Other- Thermal degradants in Plastic Product Manufacturing			
EXTRACTION				
Parameter	Data			
Life cycle description:	WI is involved primarily in the manufacture of plastic cornerguards and handles for mattresses, pallet legs and diaper pales.			
Process description:	The injection–molding process starts with the suctioning of plastic resin material into a feed chamber of the injection–molder. The different resins are held in large cardboard boxes with the suction hose inserted into the box. Additives (regrind or color additives) can be inserted into the original resin box with mixing equipment in the warehouse section of the facility. The injection–molding machines have a horizontal heating chamber where the resin is inserted and melted. The molten resin is forced into the mold where the material cools. The mold pressure is decreased thereby releasing the newly formed plastic part. The mold is then closed and the process repeats itself. Workers stand by their machines and collect and stack the plastic parts prior to packaging and shipping. Other than break/lunch times, workers stand for the entire work period. Plastics that are over–heated during the injection–molding process can release various thermal decomposition products. The products formed are potentially many and depend upon the polymer constituents and the process temperature. For polypropylene and polyethylene, the thermal decomposition products include CO and formaldehyde.			
Throughput:	This facility currently has 14 injection–molding machines; 5 to 7 of which are operating on a day–to–day basis.			
Number of sites:	investigated 1 site in Wyoming, minnesota

HERO ID:	2452612
Conditions of Use:	Rubber Product Manufacturing

EXTRACTION

Parameter	Data
Process description:	Rubber Injection Molding - In the rubber insulation molding press area, coiled rubber strips were heated in a die molding machine to produce electrical connector parts. Plastic Injection Molding - Plastic parts were injection molded using nylon or polybutylene terephthalate resins. Bulk resins were gravity-fed from a hopper to an electrically-heated extrusion screw. The melted resin was extruded under pressure into a die. The molded parts were ejected and carried by conveyor for further processing. In the past, extruders were purged (cleaned) between resin changes by increasing the temperature and pressure for approximately 30 minutes. This generated a substantial amount of smoke that was released to the plant atmosphere. However, the purge procedure was recently changed by lowering the temperature and pressure and shortening the purge time. The new purge process now takes about 10–15 minutes and produces much less smoke. In addition to the new purge cycle, a portable snorkel-type local exhaust ventilation unit equipped with a high efficiency particulate air filter and carbon sorbent material was available to capture smoke and organic compounds released if there was a need to run longer purge cycles. Paint Application - Four Spray Tech Inc. spray booths exhausted into the paint department. The booth openings were 42 inches square, and each spray booth was supported by four legs approximately 42 inches above the floor. Each booth had a paint-arresting prefilter, a pleated secondary filter, and an activated carbon final filter to absorb organic solvents. The company followed the spray booth manufacturer's recommendation of weighing the carbon filters monthly and replacing them when the weight of the carbon filter reached 12 pounds. Each booth had a manometer that indicated when the paint-arresting and pleated filters needed changing. Painters placed parts onto rotating spindles to spray a bonding paint containing carbon black pigment, toluene, xylene, and ethylbenzene. Electrical Testing and Small Component Assembly - Employees used naphtha to lubricate plastic and rubber parts during assembly. The naphtha was applied onto the parts with a trigger-type spray bottle. Once assembled, the parts were electrically tested prior to packaging and shipping. Cable Dipping and Hand Soldering - In cable dipping, employees manually dipped the end of bare copper cable into molten tin solder then placed it on a rack to cool. The ladle of molten tin was enclosed on three sides by a ventilated exhaust hood. A flexible metal duct connected the hood to an exhaust fan that discharged to the surrounding air after passing through a high efficiency particulate air filter. The company changed from a lead-based solder to a tin-based solder between our first and second site visits. In the Fisher-Pierce department employees assembled printed circuit boards using a hand-held electric soldering iron to melt the solder (60% lead, 40% tin) and complete electrical connections. A fume extractor containing an activated carbon filter operating at a flow rate of 300 cubic feet per minute was positioned directly behind the circuit board being soldered to capture smoke generated during the process. Deflashing - Deflashing removes excess plastic material from parts following molding. Employees manually loaded plastic parts into the top of the deflasher machine. The employees then removed, inspected, and sorted deflashed parts.

Study Citation:	Meyer, B., Hermanns, K. (1986). Formaldehyde release from wood products - an overview. ACS Symposium Series 316:1-16.			
HERO ID:	5946044			
Conditions of Use:	Wood panel products bonded with formaldehyde derived resins			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	During the past year, approximately 300,000 metric tons of UFR have been used for panel manufacturing in the U.S. In 1984 the annual production of UF-bonded particleboard was 5.5 mil cubic meters (3.1 billion square feet on a 3/4 inch base) in the U.S. alone. In 1984 1.1 million m3 MDF was produced in the U.S.			
Life cycle description:	70% of particleboard was used in furniture, cabinet construction and fixtures; 20% was used in conventional home construction, and 10% in the manufacture of mobile homes.			
Process description:	The most widely used wood panel products are particleboard, softwood plywood, hardwood plywood, medium density fiberboard (MDF) and waferboard.			
Throughput:	0.2 to 1 m^2 of product surface per 1 m^3 of indoor air volume			
Number of sites:	The production of UF-bonded particleboard involved 48 plants in the US. Only two plants made phenolic particleboard and only one plant produced isocyanate bonded particleboard. Production of MDF occurred in 12 plants			
Chemical concentration:	Particelboard contains between 6-8 wt% UFR. MDF contains 8-10 wt% UFR. Hardwood plywood contains 2.5wt% UFR.			
Comments:	This article talks about the factors considered when modeling air concentrations and emissions.

HERO ID:	1965315		
Conditions of Use:	Compressed Wood Product Manufacturing		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	30,000 tons of dry recovered particles with a planned increase to 50,000 tons by 1997.		
Process description:	Figures 1 and 2 provide visual depiction of process description along with materials flows. Wood-based panels from old wooden furniture, interior fitments, and production rejects are first broken into pieces 15 to 20 cm long. This can easily be done with a slow-rotating breaker, which is normally used for size reduction of bulky refuse. The pieces can be longer, but should not be shorter: this will minimize damaging effects on fibers and particles as well as surface and edge coatings which are shortened by the breaking. The furniture pieces are put into a pressure reactor which is then closed and evacuated to remove air from the panel pieces. The wood is then easily impregnated with a liquor consisting of water, formaldehyde bonding chemicals like urea and ammonia, and other chemicals to keep the pH constant. Excess liquor which not has been absorbed after 1 to 10 minutes is removed from the reactor and used for the next cycle. The impregnation also can be described as a soaking process. To achieve optimum disintegration, it is necessary that the panel pieces absorb 70 percent or more of their own weight of the impregnating solution. The impregnation can be accelerated by increasing the temperature of the impregnation liquor. After removing the excess impregnating liquor, the material is heated to about 110°C for about 20 minutes. The resin is mainly dissolved by hydrolysis. The remaining wood structure is destroyed by thickness swelling. Coatings, fasteners, hinges, and other pieces are separated from the wood fibers and particles. The pressure container can be opened and emptied for the next disintegration cycle. The disintegrated material can be machine-screened or wind-sifted. Optimum screening results will be achieved with a screening drum. The screening itself is very easy because the wood fibers and particles are very small and are easily separable from the coatings, hinges, and fasteners. The recovered wood fibers and particles have a moisture content comparable to fibers and particles of fresh wood. They can be dried and processed separately or together with fresh material using the same procedures as in a usual production line. The separated rejects also can be partly recycled. Metals can be separated, and solid wood pieces and undisintegrated panel pieces can be chipped for particleboard production.		
Throughput:	Throughput is described in Figures 1 and 2 but does not provide use rates.		
Number of sites:	2 industrial plants		
Comments:	MDF is medium density fiberboard.

Conditions of Use:	Recycling			
EXTRACTION				
Parameter	Data			
Process description:	To release fibers from the resin matrix, resin bindings mustbe broken. With regard to sensitivity to moisture and heatof the utilized resin in MDF, MDF wastes can be exposedto both factors (heat and moisture) as a solution to destroyresin bindings and to recycle fibers. Most of the methods studied in latest researches on recycling of wood panels are based on hydrothermal treatment. Usually, recycled fibers lose their quality as a result of these methods. When recycling MDF wastes by hydrothermal methods, first fibersare heated using steam treatment (hydrothermal) and thenthey are separated by utilization of refiner. Continuous heating at high temperatures and mechanical defibrillation cause fiber degeneration and destruction of lignocellulosic mass as well as degradation of wood polymers and decreased efficiency			
Chemical concentration:	Table 1 provides content of MDF boards: 12% UF resin content

HERO ID:	8728027			
Conditions of Use:	Manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Commercial capacity for producing formaldehyde in the United States during 1980 was over 8.5 billion pounds.			
Life cycle description:	Most of the formaldehyde produced is used on-site to produce resin for plywood, particle board, or plastics. Over 61 percent of the formaldehyde produced is used in resin production.			
Process description:	Methanol, normally received from offsite, is transferred from storage tanks and vaporized in a vaporizer. vaporized methanol, mixed with preheated air, enters the converter and is oxidized (or dehydrogenated and oxidized if silver catalyst is used) to formaldehyde. Typically, the converter has a packed tower configuration, but catalyst beds are also used. Efficiency of conversion of methanol to formaldehyde range from 65 to 90 percent for the silver process and is approximately 99 percent for the metal oxide process [22].After conversion, the hot formaldehyde gas (the reactor is generally operated at approximately 635QC [22]) is cooled in anaftercooler to a temperature of about 70°C and then absorbed inwater. Aqueous formaldehyde solution is recirculated through the absorption tower until the desired concentration 1s achieved. If a silver catalyst is used in the converter, the product is concentrated in a distillation column, a step in which methanol 1s also recovered. Formaldehyde is generally stared as a 50 percent solution at 50°C (which helps prevent its spontaneous polymerization to form paraformaldehyde).Diagrams given on PDF Pg. 6			
Number of sites:	Fifty-two plants representing fifteen companies.

Parameter	Data		
Production, import, or use volume:	120*10^6 lb/year.		
Life cycle description:	Most of the formaldehyde is used to make resin but unused formaldehyde is sent via truck or rail to customers.		
Process description:	Formaldehyde is manufactured by oxidation of methanol using aniron/molybdenum oxide catalyst. The production process takes place in two identical parallel trains as shown in Figure 2. Figure 3 is a photograph of the formaldehyde production unit inAlbany.Methanol is unloaded from a rail car to a bulk storage tank and then is pumped to the vaporizer. Air is simultaneously drawn through a primary filter and combined with the methanol. The methanol-air mixture 1s vaporized and fed to the converter, which consists of vertical catalyst-filled tubes. Dowtherm A®, a coolant, is pumped through the outside of the converter and removes the heat of oxidation from methanol conversion. Dowtherm vapor iscondensed and recirculated to the Dowtherm separator, and then to the converter. Hot formaldehyde gas, produced in each converter tube, is fed to the aftercooler. Cooled gas from the two parallel aftercoolers is united at the base of a single atmosphericabsorber column. Liquid effluent from the absorber, containing50-51 percent formaldehyde by weight, is stored in storage tanks.Gas emitted from the top of the absorber column, consisting mostlyof nitrogen and oxygen, passes through a demister and is recycledto the methanol vaporizer through the compressor. An oxygenganalyzer is used in-line to control the oxygen content of the airfeeding the vaporizer to reduce the explosion hazard. The entireprocess has not been modified since initial startup in 1973.		
Chemical concentration:	The site produces 37% formaldehyde solution.

HERO ID:	8728034			
Conditions of Use:	Manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	This plant uses a metal silver catalyst to convert methanol to formaldehyde at a rated capacity of 50 million pounds per year.			
Process description:	Formaldehyde is produced by a silver catalyst process. This process is based on the dehydrogenation-oxidation reaction of methanol as it passes through a silver catalyst bed. Conversion efficiency of the process can range from 65% to 90%, depending on the age and retention time of the catalyst bed. Methanol recovery and concentration of the formaldehyde solution is normally necessary to yield a usable product. Methanol, delivered by rail tank car and stored in a large bulk storage tank, is mixed with filtered air and vaporized. The methanol-air mixture is fed through manifolds to individual tubular reactors containing the silver catalyst and is converted to formaldehyde. The hot gases are quenched with a weak formaldehyde solution, in a spray box, producing a 40% formaldehyde, 20% methanol solution. This solution is cooled in a heat exchanger and stored in interim storage tanks. The scrubbed gas from the spray box passes through two spray towers and a packed tower. It flows countercurrent to laboratory wastewater and fresh water introduced in the packed tower. The water flows from the packed tower back through the spray towers and becomes the weak formaldehyde solution which is fed to the spray box. The residual gas from the packed tower is then released to the atmosphere. This exhaust gas contains approximately 73% nitrogen and 20% hydrogen, but little or no formaldehyde. The 40% formaldehyde solution from the spray box is stored in a set of interim product tanks and is concentrated to 50% formaldehyde in a distillation column. A scrubber is located on this tank to condense and hence control formaldehyde emissions from it. Methanol removed to concentrate this solution is recovered and recycled to the methanol shift tank, and product (50%) formaldehyde solution is sent to steam-heated storage tanks. Formaldehyde shipments are prepared in a blending tank where the formaldehyde content is adjusted to meet the customer specifications. The product is then piped directly to an adjacent plant or loaded onto tank trucks or rail cars for delivery.			
Chemical concentration:	The plant produces 50% formaldehyde solution which is blended with water or methanol to meet customer specifications.

Parameter	Data			
Production, import, or use volume:	The plant has a rated capacity of 160 million pounds per year (on a 37 percent basis).			
Process description:	Formaldehyde is made in this plant by a combination oxidation-dehydrogenation process, using silver oxide as a catalyst: [Figure on PDF Pg. 11]. Figure 2 is a block flow diagram of the process used in this plant.As shown in the figure and the equations above, methanol and air are the raw materials for the process. Air is brought in with a positive displacement blower and passes through a scrubber, which conditions and cleans the air prior to entering the reactor.Methanol is brought from off-site in tank trucks (Figure 3) andstored onsite in a tank. It is piped into the vaporizer, mixedwith air and enters the reactor (Figure 4). The preheated mixtureis not in the explosive limit envelope for methanol-air mixtures.The temperature of the reaction is controlled to optimize yields.Since the oxidation reaction is exothermic, waste heat is recoveredas shown in the block diagram. The reactor system contains thesilver catalyst. The product gas contains a considerable amount ofhydrogen and unreacted methanol.The product gases are passed directly to a series of countercurrentscrubbers that comprise the absorber. This cools the gasesand dissolves the formaldehyde in water (Figure 5).The off-gas from the absorber contains hydrogen and nitrogen withtraces of formaldehyde and methanol. This is burned and the heatrecovered (Figures 6 and 7) and used in the process (vaporizer).The effluent gas from the burner is primarily nitrogen, watervapor, and carbon dioxide. The burner is designed to give a99 percent combustion efficiency.The product stream from the absorber is an aqueous solution offormaldehyde (up to 50 percent, as desired). It also containssome methanol and formic acid.Products of varying strength are blended to create products required for specific sales. The blended products are loaded intotank trucks (95 percent) (Figures 8 and 9) or railroad tank cars(5 percent).			
Chemical concentration:	The product stream from the absorber is an aqueous solution offormaldehyde (up to 50 percent, as desired). It also containssome methanol and formic acid.

HERO ID:	8728037			
Conditions of Use:	Manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	This plant was selected for a preliminary industrial hygiene surveybecause of its moderate production of about 100 million pounds of formaldehyde per year, its use of metal oxide catalyst, and its southeastern location.			
Process description:	Formaldehyde is manufactured by the patented Formox process, shown in Figure 2, using a metal oxide catalyst. Methanol, delivered daily to the plant by rail or truck and stored in a bulk storage tank, is pumped into the vaporizer and vaporized. The vaporized methanol is mixed with filtered air and combined with the absorber offgas, then enters the converter where it passes through tubes filled with iron-molybdate oxide catalyst and is oxidized with up to 99% conversion efficiency according to the following exothermic reaction: [PDF Pg. 11].Dowtherm®, circulated through the converter jacket to control theconverter temperature, is used to remove the heat of reaction andproduce low pressure steam for on-site consumption. Formaldehyde vapors exit the converter, are cooled in the aftercooler and absorbed in a 25-stage absorber. After formic acid is removed in a purification step, the liquid formaldehyde is transferred to a shift tank. The contents of the shift tank are transferred into the blend tank once per shift to adjust the formaldehyde concentration. The product formaldehyde is stored in one of the tanks in the formaldehyde tank farm. The process has been operating as described since plant startup in 1970.			
Chemical concentration:	The plant, constructed in 1970, produces 50 percent formaldehyde which is used onsite to produce resins.

EXTRACTION				
Parameter	Data			
Production, import, or use volume:	100 million lbs/year/site			
Life cycle description:	Site manufactures and also produces resin that it sold to local plywood and particleboard manufacturers			
Process description:	Formaldehyde is manufactured by methanol dehydrogenation. Hydrogen gas and residual methanol produced in the process and oxidized with air provides heat needed for the dehydrogenation reaction.Initially, methanol is pumped from a rail car to a bulk storage tank and then to a vaporizer, where it is vaporized. Air, after passing through a primary filter and water wash cleaner, is preheated and combined with vaporized methanol just prior to a converter containing crystalline silver catalyst. The formaldehyde gas from the converter is fed to an absorber where the formaldehyde and unreacted methanol are cooled and absorbed in water. The resulting solution is pumped from the bottom and middle of the absorber through heat exchangers to cool the solution which is partially recycled to the absorber. The liquid effluent from the bottom of the absorber is pumped through another heat exchanger prior to being fed into a distillation column. Off-gas from the absorber consisting of 80 percent nitrogen and 20 percent hydrogen is used as fuel in an incinerator. Excess methanol is removed and a 50 percent formaldehyde solution (50% formaldehyde, 49 percent water and 1 percent methanol) is produced in the distillation column. This product solution is passed through a product cooler and stored at 55°C in a bulk storage tank. Methanol vapors off the top of the distillation column are condensed and recycled to the methanol bulk storage tank when not recycled to the distillation column forrefluxing.			
Chemical concentration:	50 percent formaldehyde solution (50% formaldehyde, 49 percentwater and 1 percent methanol) is produced in the distillation column.

Conditions of Use:	Processing: Wood Product Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	Description of ProcessesThe wood particles are first graded, coarse particles for the core and the finer particles for the face. The resin is sprayed onto the particles as they fall through a blending chute. The resin-coated particles are then conveyed to bins from which layers are coated onto large, metal caul plates; two core layers between two face layers.Using an indexing mechanism, the caul plates carrying unformed boards are loaded into a magazine from which the press will be loaded with a stack of particle-laden caul plates. At the conclusion of the press cycle, the stack is pulled out of the press and automatically unloaded one at a time onto a conveyor belt. A blast of compressed air blows loose particles from the press at the end of the cycle.Having been separated from the caul plates, the newly formed boards are conveyed to the cooling wheel. This apparatus is like a paddle-wheel with theboards resembling fins. The boards are picked up on one side and passedthrough a 1800 arc to the other side where they are mechanically unloadedand stacked.After initial cooling on the wheel, stacks of boards are taken to a stagingarea to await sanding, sizing and shipping. For all operations, the boardsare either moved in stacks with forklift trucks or transported singly onmechanical conveyors.

EXTRACTION				
Parameter	Data			
Process description:	To make fiberboard, heat and pressure are applied to a thick layer of wood fibers and resin. After cooling, the panels are sanded and trimmed to the desired size. The wood particles are first blended with the resin and wax. Then the mixture is conveyed to bins from which it is deposited in layers (two core layers between two face layers) on a conveyor belt. Two preliminary press operation impart sufficient rigidity to the unformed boards to enable them to be individually placed in a loader. During the time the press is applying heat and pressure, the loader is being refilled, and the boards most recently discharged from the press are being passed through the cooling wheel. A blast of compressed air blows loose particles from the press at the end of the cycle. The cooling wheel is like a paddle-wheel with the boards resembling fins. The boards are picked up on one side and passed through a 1800 arc to the other side where they are mechanically unloaded and stacked. Initially the boards are oversize and somewhat rough. Before being shipped, they are sanded, sized, and usually stored for some period of time. For all operations, the boards are either moved in stacks with forklift trucks or transported singly on mechanical conveyors.

Conditions of Use:		manufacture		
EXTRACTION				
Parameter		Data		
Process description:		The simplest veneered panel consists of three plies, a face and a back veneer glued to each side of a core. Additional plies may be added to make a panel which is stronger and more stable dimensionally. An established way to achieve a high rate of production is to reduce the glue-curing time by heating the glue while pressure is being applied to the panels. One way to do this is to heat the metal plates which apply the pressure, generally referred to as a "hot-press" process. Another way is to generate heat in the glue-line with radio-frequency (R/F) radiation in much the same way that food is cooked in a microwave oven. In this "R/F-press" process, the hydraulic press only applies pressure. "Cold-press" processes, those for which pressure is applied while the boards are maintained between 60 and 100 deg F, require much longer periods of time for the glue to cure. For most applications, the glue which currently provides the best performance for the least cost is a urea-formaldehyde (U/F) resin adhesive.

EXTRACTION				
Parameter	Data			
Process description:	The warehouse operations consist of the following stepwise process: Clothing is received from the manufacturer (over 400 manufacturers supply Commonwealth Trading) either in boxes or hanging racks and brought into the warehouse through 10 shipping and receiving doors. The shipment is forklifted from the receiving area to the "T" area, where it is unpacked and placed on hangers and placed in the conveyor system. Clothing is manually pushed through the conveyor system to the temporary storage area "A". In the "B" & "C" areas, the clothing is arranged by size and ticketed. The stamping of tickets is done in an adjacent area. The ticketed garments are then moved to the upper floor where they are further arranged by size, color. etc. If not needed for immediate shipment, the garments are placed in holding area "Y". When ready for distribution to retail stores, the selected clothing is conveyed back to the first level. coded for distribution and boxed. First shift is primarily concerned with the receiving aspects of the operation; second shift concentrates on packing and shipping to retail outlets .

Conditions of Use:	Processing as a reactant

EXTRACTION	
Parameter	Data
Process description:	For the resin synthesis procedure, aqueous formaldehyde at a concentration of 37% by wt and phenol were loaded in a ratio of 2.5 in a kettle equipped with a mechanical stirrer. After homogenization, a 50% by wt NaOH solution was added drop-wise so as to obtain a phenol :NaOH ratio of 1:0.15. The mixture was heated up to 65 deg C in 15–20 min and kept at this temperature for 100 min. The mixture was then cooled to 30–40 deg C and a determined amount of formaldehyde scavenger (NH4OH at 28% by wt) was added. The final viscosity of the PF-resin was of 20±1 cP at 25 deg C. The various treating resins were obtained by mixing the PF-resin with pyrolytic oil at different ratios of substituted phenol. Phenol substitutions tested were 50%, 75% and 85% on a weight basis; hereafter the treating resins were named as R350, R375 and R385 according to the percentage of pyrolytic oil present. The resins were stored at 4 deg C until use.
Chemical concentration:	concentration of formaldehyde was 37% by wt

EXTRACTION				
Parameter		Data		
Process description:		Most fiber glass and rock and slag wool (mineral wool) insulation and acoustical products come in the form of rigid batts, rolls, boards, or panels. Since glass wool and mineral wool fibers are inorganic and chemically inert, that rigidity is achieved through the application of a binder, essentially a thermosetting polymer that holds the fibers together to form a continuous network. Atypical process for manufacturing fiber glass and mineral wool insulation involves spraying aqueous solutions of binder precursors (silane, resins, de-dusting oil, and, in some cases phenolformaldehyde resins) on fibers immediately after those fibers are formed and attenuated. The combination of fibers, water, and binder precursors are then conveyed to the curing oven where the water is driven off and the binder is thermally set, forming the final rigid bonded product...It is important to note that the binder does not uniformly coat the fiber surface; instead, the process is designed to deliver only isolated binder droplets at the junctions of fibers in order to achieve the desired mechanical properties. pg. 3

EXTRACTION				
Parameter	Data			
Process description:	Sound and degraded logs were chipped using a ring type flaker. A hammer mill was then used to reduce the chips into smaller particles. The wood particles were dried to moisture content (MC) of 3%. The dried particles were classified into suitable sizes by a screen for use in the core and face layers. After that, 9 and 11 wt% urea formaldehyde resin with a solid content of 55% was applied to particles used in the core and surface layers by a pneumatic spray gun. As a resin hardener, 1 wt% ammonium chloride with a concentration of 25% was used in the blending process depending on the solid content of the adhesive. Handformed mats with dimensions of 600 mmx600 mm were pressed in a hot press at 150°C with a pressure of 2.5 MPa for 6 min to obtain a thickness of 12.0 mm. The average target density of all the particleboards was 0.65 g/cm3 . As a result of the production process, a total of 12 panels, 2 for each type of particleboard, were manufactured. All the panels were then acclimatized at 20°C and 65% relative humidity until they reached equilibrium MC. (pg 2)

Parameter	Data			
Process description:	The process that used formaldehyde in a factory which made printed circuit boards is the metalization step. After a thin coating of copper has been applied to sheets of fibrous glass, they are placed in a palladium chloride solution which deposits palladium on the exposed fiberglass-epoxy board at the sites where the holes have been drilled. Immersion in a copper deposition solution containing copper sulfate and formaldehyde follows, resulting in copper being deposited onto the palladium-covered epoxy fiberglass as well as the copper coating of the board...[description cont'd]

EXTRACTION				
Parameter	Data			
Process description:	The constructed cabinets are finished by spraying them with a series of stains, sealers, and/or paints. Stain is usually applied with compressed air sprayers. All of the spraying is done in ventilated booths manufactured by DeVilbiss. For smaller parts, such as doors, the employee would mount the part to be sprayed on a jig inside a booth, spray the part, and then remove it and stack the part on a cart outside the booth. When all of the parts are sprayed, they are moved to a central drying area. For larger parts, such as a cabinet body, the part is received on a cart, positioned in a booth, sprayed, and then moved to the central drying area. For some stains, the part is immediately wiped off with a shop cloth after spraying and before being moved to the drying area. After drying the part is again sprayed with a sealer and moved back into the central drying area.			
Chemical concentration:	Varnish (% by weight): 0.28% formaldehyde

HERO ID:	192040		
Conditions of Use:	Incorporation into article- Wood Product Manufacturing- Particleboard and fibreboard		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	Information from the Australian Wood Panel Association (AWPA) indicates that 932 000 m3 MDF and 965 000 m3 particleboard were manufactured using formaldehyde resins in year 2001-2002. Information from Australian Customs indicates that approximately 233 000 m 3 wood panel products were imported in Australia in financial year 2001-2002.		
Life cycle description:	These wood panel products have both industrial and do-it-yourself (DIY) applications for decorative, structural and industrial purposes, such as shelving. Decorative applications include furniture, shelving, panelling/partitioning, mouldings and doors. Examples of structural applications are domestic and commercial flooring, access flooring, concrete formwork and exterior signs.		
Process description:	The formaldehyde resins are charged into storage tanks and injected and mixed with refined wood fibre through an enclosed system. The particleboard and MDF are rolled and pressed ina semi-enclosed area during the hot press stage (the temperature is 160oC to 200oC) where resins set. The types of formaldehyderesins used in this industry include urea, phenol, melamine formaldehyde resins and some combination of these resins, such as melamine urea and melamine urea phenol formaldehyde resins. Figure 7.5 (p. 69) provides a flowchart.		
Chemical concentration:	the concentrations of free formaldehyde in theresins used in this industry range from < 0.2% to 0.5%

Study Citation:	NICNAS, (2006). Priority existing chemical assessment report no. 28 formaldehyde.			
HERO ID:	192040			
Conditions of Use:	Incorporation into article- Wood Product Manufacturing- Plywood			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	According to the information from the Plywood Association of Australia (PAA), 189 533 m3 of plywood and LVLwere produced in the year 2001-2002 with total consumption of 3340 tonnes phenol formaldehyde and 500 to 850 tonnes of urea formaldehyde resins. PAA represents manufacturers who produce approximately 98% of plywood and LVL in Australia. PAA advised that Australian-made plywood occupies 55% of the Australian market. Information from Australian Customs indicates thatapproximately 74 000 m3 plywood products were imported in Australia in financial year 2001-2002.			
Life cycle description:	The types of plywood products used in Australia include structural plywood, concrete formwork plywood, marine plywood, exterior and interior plywood, and overlaid and composite plywood. Products are used within Residential buildings including mobile homes, such as caravans and manufactured homes. Residential building applications include LVL framing, flooring, bracing, plywood webbed beams, roofing, cladding, interior wall and ceiling linings, plywood in domestic wet areas; Building components for commercial and industrial structures including relocatable buildings (classrooms, offices etc.). Structural LVL and plywood components for commercial and industrial structures includeflooring, stressed skin panels, beams, arches, gussets, portal frames, and bracing walls; Material handling, such as pallets, shelving, containers, bins and transport equipment; Construction on site applications, such as structural ramps, overheadprotection barriers, runways etc.; and DIY in a wide range of projects, such as flooring, wall and ceiling lining,boat building.			
Process description:	Phenol formaldehyde resin, which is the predominate resin (approximately 88%) used in this industry, is used for bonding structural, exterior and marine plywood and structural LVL. Urea and melamine urea formaldehyde resins are usually used for interior and some formply products. Formaldehyde resins are delivered in tankers and transferred into a holding tank from where they are pumped into enclosed mixing vessels and mixed with extenders (wheat flour), fillers (shell flour) and water. The mixed resin is then pumped into glue spreaders and applied to the veneer using rubber rollers or pressurised curtain coaters, which is an open process. The spread packs of veneerare then cold pressed and finally hot pressed at about 140 C, where the formaldehyde resins are set.			
Chemical concentration:	Formaldehyde resins containing < 0.2% to up to 5% free formaldehyde are used in the manufacture of plywood and associated structural veneer based products, such as laminated veneer lumber (LVL).

HERO ID:	192040			
Conditions of Use:	Incorporation into article- Paper Manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	Paper treating is an automatic, continuous processinvolving two resin stages. In the first resin stage, urea resin is pumped from storage tanks to an automatic closed batching station where additives, water and a catalyst are added to help with paper saturation and promote curing in later drying and laminating processes. This mixture is pumped into the first stage bath wherethe paper for impregnation is automatically fed by rollers through the bath at a speed of approximately 40 meters per minute and is impregnated as it passes through the bath. The bath is open at the top. The paper then passes into a closed oven with temperatures ranging from 120°C to 170°C for drying. In the second resin stage, melamine resin is pumped into an automatic closed batching station and mixed with a release agent and a catalyst. This mixture is then pumped into a second stage resin application station where the paper (after the first resin stage) is fed through the rollers and is coated with the resin mixtures automatically. The coated paper then goes into the second drier. Finally, the paper is automatically cut to length and stacked in plastic wrapped packs for shipment.			
Chemical concentration:	Urea and melamine resins containing up to 1.5% free formaldehyde are used in paper treating and coating.

HERO ID:	192040			
Conditions of Use:	Incorporation into article- Textile Finishing			
EXTRACTION				
Parameter	Data			
Life cycle description:	The formaldehyde resin products used in the textile industry include printing inks, dyes and textile finishing products.			
Process description:	Textile printers use formaldehyde resins as a cross-linking agent in acrylic binder systems for pigment printing of polyester/cellulose or synthetic materials. The formaldehyde resin is diluted with water and mixed with print paste for approximately 10 minutes in a vat by either manual stirring or mechanical mixing. Typically 1% to 3% of the resin product is used in the print paste depending on the depth of shade of the print required. The print paste is then transferred onto the fabric using a print screen (flat bed printer). The print is generally cured at 150 oC for up to 3 minutes to cross link the acrylic resin binder.At large textile dyeing enterprises, formaldehyde resin is pumped from drums into a large storage/dispensing vessel and then transferred to the dyeing equipment where the product is diluted at a rate of 1-2 g/L. The temperature inside the dyeing machine is about 100 oC. The product is rinsed off after dyeing and the water goes to trade waste. The operation is a daily activity and manual processes occur at some smaller sites.Formaldehyde resins are used as cross-linking agents for cotton fabric and other cellulotics to produce a finish that resists hydrolysis and is inert, durable and unaffected by heat or bleach. Formaldehyde resin is poured into an open tank and diluted with water to ratios of 1:10 to 1:20. Textile finishing processes includepadding, drying, and curing. The padding is normally done by immersing the fabric in the resin aqueous solution, followed by squeezing it between two rollers, and finally drying and curing. The durations of the padding vary depending on the type of fabrics			
Chemical concentration:	The concentrations of free formaldehyde inthese products are generally < 2%.

HERO ID:	192040		
Conditions of Use:	Industrial use of adhesive- sand binder		
EXTRACTION			
Parameter	Data		
Life cycle description:	At foundry sites, a variety of iron castings are produced for the automotive industry		
Process description:	At sand coating sites, the resin is pumped into a mixer at a rate of 1% to 1.2% resin by weight of sand. At some sites, the resin is decanted from drums manually into a measuring cup and then poured into a mixing vessel. Mixing normally takes about 5 minutes and the coated sands are then decanted into bags ready for core making at foundries. This is a batch operation and the frequency of the operation varies from site to site.Foundry using sand as the moulding material consists of six basic processes: pattern making, core making, moulding, metal melting and pouring, and casting cleaning (fettling). Core making is the process of creating solid shapes from sand using a variety of binding system. These solid shapes, called ‘cores’, determine the internal cavities of the casting. Hot, warm and cold box core making techniques are used in the foundry. About 90% of the cores are produced by hot and warm box technologies, using urea formaldehyde resin, phenol, and furfuryl alcohol systems.Typically, the sand coated with formaldehyde resins is blown into a hot mould (with temperatures around 110 C) where formaldehyde resin melts and functions as a bonding agent to make cores. At larger enterprises, sand coating and core making occurs in an enclosed system. Drums containing formaldehyde resins are connected to an automatic dosage system, which supplies a set dosage of the resin into core making machines		
Chemical concentration:	The hot box resin system contains typically 5% to 6% free formaldehyde in the resin, whilst the warm box typically contains 2% to 3% free formaldehyde.

The aqueous solutions are manually dispensed into specimen jars and used for fixing human tissues and organs after autopsy. [Detailed process descriptions, pg. 73-74]		
Chemical concentration:	The most commonly used solutions are neutral buffered formalin solutions containing 4% formaldehyde. The solutions are either purchased from suppliers already in aliquot containers/specimen jars or made on site by diluting concentrated formalin solutions containing 20% to 32% formaldehyde.

Study Citation:	NICNAS, (2006). Priority existing chemical assessment report no. 28 formaldehyde.			
HERO ID:	192040			
Conditions of Use:	Manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Formaldehyde is manufactured in Australia as aqueous solutions known as ‘formalin’, at approximately 55,000 tonnes per annum (calculated as 100% formaldehyde). Formalin and products/mixtures containing formaldehyde are also imported at approximately 90 tonnes (100% formaldehyde) per year. In addition, approximately 700 tonnes per year of paraformaldehyde (a significant source of formaldehyde) is imported. The global production of formaldehyde in 1999 was estimated 5 to 6 million tonnes (Asia: 1 to 1.5 million tonnes, North America: 1 to 1.5 million tonnes, Western Europe: 2 to 2.5 million tonnes). A global production figure of 12 million tonnes in 1992 was reported. Formaldehyde is listed on the Organisation for Economic Cooperation and Development’s (OECD) List of High Production Volume (HPV) chemicals, i.e. production volume of 1000 tonnes or more in at least one OECD country (OECD, 2004).			
Life cycle description:	The main industrial use of formaldehyde and paraformaldehyde is for the manufacture of formaldehyde-based resins, which are widely used in a variety of industries, predominantly the wood industry. Formaldehyde is also used directly or in formulations in a number of industries including medicine-related industries (such as forensic/hospital mortuaries and pathology laboratories), embalming in funeral homes, film processing, textile treatments, leather tanning, and a wide range of personal care and consumer products. The concentrations of formaldehyde in these products range from 40%, such as in embalming and film processing solutions, to < 0.2%, such as in the majority of cosmetics and consumer products.			
Process description:	Various manufacturing methods were used in the past, but only two are widely used today: the silver catalyst and metal oxide catalyst processes (IARC, 1995). Formaldehyde is manufactured in Australia by catalytic oxidation of methanol. Two methods are used; one uses a silver catalyst and the other a metal oxide catalyst. As formaldehyde is produced in gas form, it is absorbed into water during manufacture.			
Throughput:	The main industrial use of formaldehyde and paraformaldehyde is for the manufacture of formaldehyde-based resins			
Number of sites:	Four companies manufacture formaldehyde at five sites around Australia.			
Chemical concentration:	The aqueous solutions are called formalin and the concentrations of formaldehyde in formalin range from 37% to 54%.

HERO ID:	192040			
Conditions of Use:	Import			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	The quantity of imported formaldehyde is approximately 76 to 109 tonnes per annum.The total reported importation of paraformaldehyde is shown in Figure 7.3 and is approximately 700 tonnes per year. It was reported that most imported paraformaldehyde is used in resin manufacture.			
Life cycle description:	The information provided to NICNAS indicates that more than 250formaldehyde-containing products, such as formaldehyde resins, film processing products, surface coating products, and preservatives, are imported. The concentrations of formaldehyde in the imported products vary widely, however, the majority of them are less than 1%. Imported products are either further incorporated into end products or used directly by end users. Some end use products containing formaldehyde are imported and sold directly to the general public. Examples include cosmetics products and other consumer products, such as fabric softener, surface liquid cleaners and dishwashing liquids.			
Process description:	Formalin is imported in packaging of various sizes including 220 kg drums, 20 L drums, 22 kg carboys, 2.5 L bottles, 500 mL bottles and 10 mL ampoules. Imported formalin is transported in pallets in full container loads or on trucks mainly by road. The majority of imported formalin is used in resin manufacture and as laboratory reagents [in Australia].			
Chemical concentration:	Paraformaldehyde is imported as prills or powder in 25 kg bags. The concentrations of formaldehyde in these prills/powder range from 81% to 99%.

EXTRACTION	
Parameter	Data
Life cycle description:	The resin powder does not contain any free formaldehyde and is used as a binder in the manufacture of abrasive products, such as grinding wheels, brake components (for example, brake linings), and refractory products. These products are typically compressionmoulded and then heat cured
Process description:	The manufacture of resins is a batch process and conducted in enclosed systems. The manufacturing process varies from site to site. Typically, formalin is transferred through a fixed piping system and charged into resin reactors. Manual charging of formalin from drums occurs at some smaller resin manufacturingsites. In the situation that paraformaldehyde is used, it is charged manually from sealed bags into the reactor. Each batch typically takes about 8 to 12 hours, but can vary from 5 to 30 hours depending on the technical grade of the resin. Decanting of the resins is via a closed pipe system to storage tanks on site fromwhich it is pumped to drums, bulk containers or bulk tankers for road transport. Some workplaces decant the resins manually into 8 to 200 L drums.Solid phenol formaldehyde resin powder is also manufactured in Australia. The molten phenol formaldehyde resin is dropped from the reactor onto a cooling floor where it becomes a brittle solid, which is then manually broken into lumps. The lumps are subsequently blended with curing agents and ground to a powderwhich is then packed in 15 kg or 700-800 kg bags for sale.
Chemical concentration:	The majority of the formaldehyde resins contain < 0.2% free formaldehyde, but some contain > 0.2% depending on the applications of the resins. For example, some fibreglassresins contain up to 13% free formaldehyde. Solid phenol formaldehyde resin powder does not contain any free formaldehyde.

HERO ID:	192040			
Conditions of Use:	Formulation into mixtures			
EXTRACTION				
Parameter	Data			
Process description:	In general, formulation is a batch process, in which measured amounts of formaldehyde or product containing formaldehyde and other components are added to mixing vessels and blended to form end products. The product is then transferred to containers and dispatched to customers. In general, manual processes occur in small batch productions, such as formulation of anti-graffiti wall sealer. Typically, formalin or product containing formaldehyde is decanted into a vessel for weighing before being poured into an open tub and stirred. Decanting is done with a small jar and funnel. Equipment is cleaned manually between different products with either water or cleaning solvents. For larger-scale production, such as detergents and disinfectants formulations, formalin or product containing formaldehyde is either directly poured into a mixing tank using a drum lifter or is transferred via a transfer pump. Other ingredients are then added, followed by mechanical stirring. For some formulations, formalin or product containing formaldehyde is premixed with other ingredients before adding into the main mixing vessel. The mixing operation is usually conducted under closed or partially closed conditions and the final product is pumped into drums for transport to customers. Decanting is usually an automated process. Table 7.4 provides durations and frequencies.			
Chemical concentration:	Table 7.4 (p.65) contains chemical concentrations of formulated products.

Conditions of Use:	Repackaging			
EXTRACTION				
Parameter	Data			
Process description:	Most repackaging of formalin or product containing formaldehyde is from 200 L drums to smaller containers, such as 5 L and 20 L containers. They are decanted into smaller containers either through a pump (enclosed process) or fed via gravity. Repackaging is usually not a continuous operation and the duration and frequency of the operation vary from site to site. Formalin is also repacked from large storage tanks. The material is pumped into the storage tanks and transferred into various size containers using a pump and an enclosed tubing system. Manual and open repackaging processes were reported during repackaging paraformaldehyde powder (see Table 7.5). It is assumed that enclosed processes may also occur in Australia.

Conditions of Use:	Commercial Use- Photoprocessing			
EXTRACTION				
Parameter	Data			
Process description:	The products are in 9L or 19 L plastic drums and carried from the storage area to the film processing area. Workers open the cap and insert a tube into the drum. The product is pumped into the bottom of an enclosed wash tank (final bath) in an enclosed machine. Water is injected at the same time to dilute the solution. The formaldehyde concentration in the working solution is < 1%. The aerial film goes through the final bath before passing a dryer (at 140C) and being developed. The wash goes to drain after use. The empty drums are sent to landfill or rinsed with water for re-use. Most commercial film processing sites use enclosed machines (processors) that have a final bath tank specifically for formaldehyde aqueous solutions. The concentrations of formaldehyde in the solutions range from 0.1% to 15%. The solution is poured into the tank and diluted with water in the required ratios ranging from 1:100 to 1:1000. Typically, the processors are operated for an average of 4 or 5 hours a day, 5 days a week. The final bath is replenished about 1 to 2 times a week. The waste generated during film processing either goes to drain or is collected in a container for disposal.			
Chemical concentration:	Formaldehyde products containing high concentrations of formaldehyde (20% to 35%) are used in final baths of some specialised film processing, such as aerial film processing.

Conditions of Use:	Commercial Use- Lab Use			
EXTRACTION				
Parameter	Data			
Process description:	Large use (forensic/hospital mortuaries/anatomy labs): the concentrated formalin solution is manually poured into an enclosed mixing system, diluted with water in ratios of 1:5 to 1:8 and mixed with other ingredients. These aqueous solutions are stored in enclosed large tanks (up to 1000 L) and are automatically decanted into smaller containers before end use. The aqueous solutions are manually dispensed into specimen jars and used for fixing human tissues and organs after autopsy. Small use (pathology laboratories): concentrated formalin solutions are diluted manually with water using measurement equipment and funnels.The neutral buffered formalin solutions already aliquoted into specimen jars are used in hospitals and doctors’ rooms for preserving human tissues from biopsy. The specimen jars are sealed and sent to pathology labs. In pathology labs including histopathology labs, human tissues are taken out of the specimen jars and accessioned (‘cut-up’) to certain sizes or shapes which are then placed on a tray that goes through a processing machine (‘processor’). Accession is undertaken manually on benches equipped with ‘down draught’ extraction systems. The processor has a number of containers holding different chemical liquids including neutral buffered formalin solution, which needs to be topped up regularly (up to once a day in large laboratories). During the topping up, the container is taken out of the processor and the solution is poured in using a funnel. After the processing, the specimens are waxed and cut to prepare slices for microscopic observations [More description provided in source]			
Chemical concentration:	The most commonly used solutions are neutral buffered formalin solutions containing 4% formaldehyde. The solutions are either purchased from suppliers already in aliquot containers/specimen jars or made on site by diluting concentrated formalin solutions containing 20% to 32% formaldehyde.

Conditions of Use:	Commercial Use- leather and fur tanning			
EXTRACTION				
Parameter	Data			
Process description:	Workers dilute the formalin solution at a ratio of 1:10. The working solution is then added manually to an enclosed processing drum. This operation takes about 5 minutes. Furs are added into the drum and mechanically rotated for 18 to 24 hours. The solution is drained before furs are removed manually to an open tub. The tanned furs then go through drying, staking and other numerous processes. The NICNAS survey data indicates ... one leather processing company uses it 6 times a year.Products containing 10% to 15% formaldehyde are used daily in general leather tanning. The processes are similar with the fur tanning, except the addition of the product from intermediate bulk container to the processing drum is via an enclosed system.			
Chemical concentration:	Fur tanning uses formalin containing 37% formaldehyde, which is diluted at a ratio of 1:10. For leather tanning uses 10% to 15% formaldehyde daily in general leather tanning

HERO ID:	3001257			
Conditions of Use:	Use of fabric, textile and leather products			
EXTRACTION				
Parameter		Data		
Life cycle description:		Formaldehyde is added to textiles for resistance to wrinkling, stability, good dimensional stability, compatibility with finishing agents, color resistance, maintenance of fabric whiteness, and environment protection for application of resins and other finishing operations.		
Chemical concentration:		Printed cotton, underside, 39.8 mg/kg; printed shirt, phosphorescent 58.5 mg/kg; shirt with an “non-iron” treatment which had 106 mg/kg formaldehyde. Fig 4 provides formaldehyde emissions in children clothes with the median around 20 mg/kg with the max at about 59 mg/kg. Men’s clothing had a max of 75 mg/kg.		
EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability		Metric 1: Methodology	Medium	Source is likely not peer reviewed but appears to be high quality data due to testing being based on European and international standard.
Domain 2: Representativeness		Metric 2: Geographic Scope	Low	Data is for Romania, a non-OECD country.
		Metric 3: Applicability	Low	The report is for a non-occupational scenario (consumer scenario) which may be useful for commercial use scenario.
		Metric 4: Temporal Representativeness	High	Data is less than 10 years old (2013).
		Metric 5: Sample Size	Low	characterized by no statistics.
Domain 3: Accessibility/ Clarity		Metric 6: Metadata Completeness	Medium	Values measured are shown graphically but are hard to interpret, methodology, sample type, and a few data points are provided in text.
Domain 4: Variability and Uncertainty		Metric 7: Metadata Completeness	Medium	Addresses variability by looking at different types of textiles from different countries. Does not address uncertainty
Overall Quality Determination			Low

Conditions of Use:	Textile Finishing			
EXTRACTION				
Parameter	Data			
Process description:	The manufacturing processes at the Woolrich plants are typical of the garment industry in general, and are basically comprised of cutting, separating, jointing and sewing, inspection, and pressing.			
Throughput:	Ten thousand square yard lots of cotton material is received and cut at the Woolrich main plant before being sent to the Avis and Howard plants. Each lot of material produces approximately 4000 shirts once received at the pant. Roughly five weeks are required for a particular lot to proceed through the manufacturing processes. Approximately 15,000 shirts are produced per week, and at a given time, 60-70,000 shirts may be in the plant undergoing one of the numerous processing operations. Thus, numerous lots of material may be present at any given time, witheach shirt being handled by 30 to 40 employees. Woolrich uses three different finishing companies to apply the wrinkle-resistantformaldehyde resin to their cotton material.

EXTRACTION	
Parameter	Data
Life cycle description: Process description:	Chemical substances in metal products : gray and ductile iron foundry A core is used to define the internal hollows desired in the casting. Cores were made both by hand and by machine. A hot shell core is produced by dumping a resin-coated sand into a heated pattern, holding the coremaking materials in place long enough to produce curing on the surface, removing excess sand from the core, and then removing the hollow-cured shell from the pattern. Employees made oil-based cores, containing linseed oil and petroleum distillates, which were baked in a gas-fired ovens to make a solid core. No-bake cores were made of a phenolic-formaldehyde binder (PEPSET I®, PEPSET II®, and PEPSET III®, Ashland Chemical Company, Columbus, Ohio) mixed with silica sand in an automatic mixer. A polymeric methylene phenylene diisocyanate (MDI) was used as the binder catalyst. A mold provides the cavity into which the metal is poured to produce a casting. Seven squeeze jolt molding machines, which use green sand containing coal dust, were used in conjunction with the deck pouring conveyor. These machines use an air-rammer to compact the sand to make a solid mold. Excess sand was removed using compressed air. The finished molds are placed on a conveyor using chain hoists or manual lifting. One large Osburn molding machine was separate from the rest and had its own pouring conveyor. A mold parting compound was used in the molding area. To produce molten iron, the plant used three electric induction furnaces with a total capacity of 3.5 tons. Each furnace had a tight fitting lid to help control fumes. The metal pouring operation was performed inside the facility using molds on conveyor systems. Molten metal was poured into a large transport ladle and transferred into small ladles with flip lids for pouring on the conveyor deck. Chain hoists were used to maneuver the ladles. The molds were allowed to cool in the location where they were poured. The molds advance to the end of the platform where they fall on the floor. The two pourers also hand-separate castings from the sand. A Bobcat front-end loader was used to load the sand reclamation system and shakeout some of the castings. The reclamation system feeds the sand muellers in the molding areas. The cleaning department had three grinders and one cut-off saw operator. The worker in charge of shipping also did repair welding. The facility used an abrasive blasting machine and a steel shot blast machine to clean castings.

Conditions of Use:	Use of Paints/Coatings			
EXTRACTION				
Parameter	Data			
Process description:	Powder coating is a dry, or solvent-free, painting process used to place a polymer coating on metal surfaces. At this facility, most of the objects to be coated are relatively small and include outdoor furniture, automobile trim, lawn and garden equipment, and other products that are likely to be exposed to harsh environments. The first step in the process is cleaning and surface preparation. The parts are placed in a steel frame wire basket approximately four feet long, three feet wide, and three feet deep. The basket is lifted by an overhead crane and sequentially dipped and soaked in a series of heated tanks containing water-based cleansers, degreasers, and surface treatment chemicals. A variety of cleaners and treatment chemicals may be used in the dip tanks. These include hydrochloric acid, chromic acid, phosphoric acid, hydrofluoric acid, zinc phosphate, potassium hydroxide, sodium hydroxide, ethylene glycol monobutyl ether (Butyl Cellosolve®), and a variety of phosphates and detergents. After surface treatment and a final rinse stage, the basket of parts is moved into a small, gas-fired drying oven. When all the water has been evaporated, the basket is removed from the oven, allowed to cool, and then pushed across the floor into the coating area. The parts to be coated are hung from racks on a continuously moving overhead conveyor and are carried through one or more ventilated spray booths. The coating is supplied as a finely divided dry powder which, according to literature reports, ranges in diameter from 5 to 100 micrometers (:m). There is currently some interest in the development of powder coatings with smaller particle sizes which would allow thinner coatings to be applied, but which might also present a greater inhalation hazard. At Modern Materials the powder coating is applied using two electrostatic spray guns, located on opposite sides of the booth. The guns produce an aerosol of electrically charged coating particles. In some cases the spray guns can be attached to a stand or reciprocating arm and no operator is required. However, if the items being coated are complex shapes, the guns must be aimed and moved by an operator. The powder is sprayed from the gun by compressed air, and particles are attracted to the metal objects by the electrical field that is developed between the charged gun and the electrically grounded conveyor. After the objects to be coated are covered with a thin film of dry powder, they are carried into a gas or electrically-heated oven where the powder melts and flows to produce an even coating. With some coating formulations the elevated temperature in the oven also cures the paint by initiating a polymerization reaction. Depending on the type of coating being used, the oven temperature ranges from about 200 to 250o C. Residence time in the oven is generally no more than a few minutes.

EXTRACTION

Parameter	Data
Process description:	Raw greige (unbleached, undyed) cloth is shipped to the facility for processing. Cloth is "plated" from rolls onto buggies, inspected, and transported to the Preparation and Finishing Department, where it is prepared for printing. The preparation process includes washing the cloth to remove starch and smoothing and stabilizing the cloth in a heat-setting tenter. Raw cotton material is further processed in a mercerization step, which is a conditioning process that results in a flatter, softer product that is more receptive to dyes. The Mercerizer machine treats the cloth with a caustic soda (sodium hydroxide) solution. The Stock-Paste carrier is used to adjust the viscosity and application characteristics of the dye. The stock paste consists of Reserve Salt Flake® (m-nitrobenzene sulfonic acid sodium salt, sulfuric acid disodium salt, and water), kelgin (a polysaccharide from seaweed), urea, sodium bicarbonate, Revatol-S® (a substituted benzene derivative), Trydet 2675® (stearic acid and a polyglycol ester), water, and up to 40% mineral spirits. Ammonium hydroxide is added, infrequently, to the pigment stock-paste. Stock paste is fed to the Dye Mixing Department ("color kitchen") through pipes. This Department is separated into two distinct areas: a computerized auto-mixing area and a manual mixing area. Eighteen "mother" colors are used to produce the desired dyecolors. The manual mixing area is used to make fine adjustments in dye color or prepare low volume colors. Dye is scooped out of vats by hand, weighed, and mixed into other vats. No powder dyes are used. In the Strike-Off Department (Sample Department), dyes are mixed by hand, and trial patterns and colors are produced on an experimental basis. Dye is added to the roller with a hand-held pump. Then the cloth, which sticks to a belt (referred to as a "blanket") having an adhesive, is drawn under the roller. The ink comes through small holes engraved in the roller, imprinting a pattern on the cloth. Several rollers may be needed to impart different colors or patterns to the cloth. In the Rotary Printing Department, dye is printed on cloth in a similar manner to that in the Strike-Off Department; except the operation is automated, and the scale of the operation is greater. Dye from the auto-mixer is transferred to the Rotary printers and is blown inside the cylinder for high volume printing. There are four rotary printers. Adhesive compounds are applied to the belts (referred to as "blankets"), which carry the cloth under the dye cylinders. Additional adhesives are added to the belts when needed. Occasionally, old adhesive must be removed from the belts; this is reportedly done with acetone and/or xylene. In the Finishing Department, three Hirano® machines are used for heat-tenting and application of soil-resist substances (Scotchgard®, Zonyl®). In addition, "resists," which are actually resins, are applied to the cloth for shrinkage control. One of the "resists," known as Permafresh LO®, mixed with water, an emulsifier, and a catalyst additive before it is applied to the fabric.
Number of sites:	1
Chemical concentration:	Permafresh LO®, contains formaldehyde at a concentration of <0.5%. This particular type of resin is designated as a low formaldehyde emission product, according to the manufacturer.

EXTRACTION				
Parameter	Data			
Process description:	The plant chemical processing (entirely by batch operation) isconducted in three separate buildings. Organic Flocculants: Polyamine and polyacrylamide products are manufactured in a modern, well-designed installation which was built in 1975. Chemical feed stocks, of various degrees of hazard, are epichlorohydrin, dimethylamine, ethylene diamine, hydrochloric acid, acrylamide monomer, isopropyl alcohol, ammonium persulfate, and formaldehyde. Major chemicals are handled in bulk from outside storage tanks, while minor ingredients are handled by drum. Various chemicals are added to large mixing kettles according to formulation via pipe transfer systems. When the batch is made it is transferred via pipe system to railroad tank cars, trucks, or 55 gallon drums. Alum is batch processed from company mined bauxite, sulfuric acid, and water in a wooden tank installation. Various amounts of bauxite and sulfuric acid, and water are added to large wooden kettles; the liquid is agitated with stirring rods; then the product is transferred to railroad or truck tank cars by pipe.Specialty Chemicals: In the remaining operable building, melamine formaldehyde resin products are being produced. The hazardous chemicals employed include formaldehyde, melamine powder, acrylamide monomer, hydrochloric acid, and sodium hydroxide solution. The manufacturing process chemicals are added to the process kettles using pipe transfers from storage tanks. (Page 4 of 23)			
Throughput:	Current (as of this paper) production 3.0 million pounds per month for specialty chemicals. (Page 3 of 23)

Parameter	Data			
Process description:	Mueller Company is a grey iron and brass foundry that produces valves for water and gas distribution service. At the time of these surveys, the Mueller Company operated a mulling operation, core room, and pouring deck operation within the brass foundry. The company prepared cores by a traditional foundry casting process using a formaldehyde-based resin system. The required ingredients (sand, clay, and binders) were mulled and transferred to the appropriate packing location. The sand core was then made by placing the mulled mixture into a core box (bench molding) or core molding machine. The sand core then passed through a curing oven. After curing, the cores were cleaned, inspected, and transferred to the pour deck of the foundry. The raw metal charge consisted of ingots, which were composed of approximately 76% copper, 12-13% zinc, and 6-7% lead. The ingots were charged into electric induction furnaces and melted. At the correct temperature, the melted charge was tapped and transferred to pouring stations. On the pouring lines, the molten metal was poured into molds and cores under local exhaust ventilation. After pouring, the molds were allowed to cool for a pre-determined amount of time. The molds were transferred to the shake-out area where the castings were separated from the mold and sand. After shake-out, cast parts were transferred to the rough grind area, where casting surfaces were ground to remove gross imperfections. As necessary, parts received final finishing, were assembled, and packed for shipment.

Parameter	Data				
Number of sites:	1				
Chemical concentration:	Bulk samples of embalming and formalin solutions were performed.Bulk sample No. 1 could not be analyzed for formaldehyde by ion chromatography due to the interfering substances present in the sample. Portions of the sample were then reacted with chromotropic acid as in P&CAM 125 . This colorimetric method could not be used since a different shade of color was formed (alcohol, phenol, and other aromatic hydrocarbons interfere with this method). Then, a titration method was attempted without any success. The pH of the solution was too low for titrating formaldehyde with standardized sulfuric acid.Bulk sample No. 2 was analyzed for formaldehyde content by titrating with standard 0. 1005 N sulfuric acid. From duplicating analyses, the formaldehyde concentration was determined to be 24. 1 mg per ml. This is equivalent to 2.4 percent formalin solution.

EXTRACTION	
Parameter	Data
Process description:	1. Gross Dissection a. the organ or biopsy is taken from a formalin solution (10%), Zenker Fixative or Bouin. b. The organ or biopsy is measured, described and sectioned. c. The sections are immersed for 4 hours in a formalin solution2. Tissue Processing a. the automated tissue processor is used. It usually has 12 positions which contain ethyl alcohol, chloroform, and paraffin. the technician hooks small metal perforated cassettes containing tissue above solutions. i) Eight of the containers hold graded alcohol (80-100%) Alcohol is used to remove water from the tissue since it is not miscible with paraffin. ii) The tissue cassette is immersed in Chloroform or Xylene to remove ethyl alcohol iii) The tissue cassette is immersed in paraffin, which firms up the tissue for cutting. b. The tissue cassette is removed from processor and is vacuumed while in molten paraffin. This process removes air from the tissue so that each cell is infiltrated with paraffin.3 Slide Preparation and Staining a. Paraffin embedded tissue blocks are serial sectioned on a microtome. b. The sections are placed in warm water or a water-gelatin solution after which the tissue sections are placed on slides to which they may now adhere. c. The slides are placed in a slide holder and heated in a oven at 60C paraffin is melted off for the most part. d. the slide holder is dipped in xylene or toluene to remove the paraffin e. the slide holder is then dipped into graded ethyl alcohol and rinsed with water. f. a typical staining procedure is as follows: i) Slides are briefly immersed in hematoxylin, a regressive stain used to intentionally overstain the tissue. ii) slides are rinsed with water and then excess hematoxylin removed with 1% hydrogen chloride in 75% ethyl alcohol. iii) slides are rinsed with water, blued with lithium carbonate for good nuclear detail and then rinsed with water again. iv) Slides are now immersed briefly in eosin, a counterstain and are then rinsed with water followed by a rinsing with 95% ethyl alcohol. v) Slides are rinsed with water and then immersed in xylene or a toluene/terpineol solution vi) slide holder is removed from xylene so that they may be coverslipped with a xylene or toluene-based mounting resin.

Conditions of Use:	Use of Adhesives and Sealants			
EXTRACTION				
Parameter	Data			
Process description:	Keokuk Steel Casting, a subsidiary of Kast Metals, Inc. produces medium-sized ferrous products used primarily for the subsequent manufacture of excavation equipment. "No-bake" type cores and molds are used in the production process. Cores are produced by means of an automated "Isocure" system, in which the core sets, or hardens, instantaneously. Ashland Chemical's Isocure I-308 (phenol-formaldehyde resin with solvents) and Isocure II-612 (diphenylmethane diisocyanate with solvents) are mixed with sand immediately prior to entering the metallic core mold. As a curing system, Ashland Chemical's Catalyst 702 (dimethylethylamine) is then blown into the mixture, the mold separates, and the core is manually removed and stacked onto skids. Molds are produced in two areas, one for small molds and one for larger molds. Pepset 2590, consisting primarily of diphenylmethane diisocyanate (MDI) and hydrocarbons, or Pepset 1590, a phenol-formaldehyde and hydrocarbon mixture, are mixed with sand and fed into molds, manually tamped down, then allowed to air set. The remainder of the process prior to metal pouring deals with combining cores and molds, which takes place in an assembly line fashion downstream of the core/mold production area. The metal pouring area is partially enclosed and ventilated via dilution ventilation. Approximately once per hour a "heat" is poured. Subsequent to metal pouring, the casts are allowed to set and harden. Once the casts are sufficiently cool, they are transported to the shakeout area where the casts are separated from the molds (Georgia Iron Works or "GIW" process). The broken molds are crushed, treated, and the sand is returned to the mold production process for reuse.

EXTRACTION				
Parameter	Data			
Life cycle description:	Formaldehyde is in the insulation as a phenol-formaldehyde binder			
Process description:	Energyloc is a weatherization contractor which sells and installs insulation for homes. Each crew of two or three loaded the materials needed for that day in their truck and proceeded to the job site. Every house or job is different. Access to the crawl space maybe from the outside or through the inside of the house. The installers enter the crawl space and, if needed, lay down a plastic vapor barrier. The fibrous glass rolls and/or batting are then passed into the crawl spaces where they are installed. Installation of the fibrous glass is accomplished by the worker lying on his back, inserting the fibrous glass between the floor joists and stapling the material to the joist. The fibrous glass insulation is also usually wrapped around the heating ducts and either taped or tied in place. The materials to which the installers are exposed to are fibrous glass fibers, formaldehyde (present in the insulation as a phenol-formaldehyde binder), cellulose dirt and dust.

Conditions of Use:	Non-TSCA

EXTRACTION	
Parameter	Data
Production, import, or use volume:	The SMSC factory processes nearly 1 million tons of sugar beets annually. The processed products and annual production rate are: granulated refined sugar (about 99.9% sucrose), 100,000 tons; beet molasses, 50,000 tons; and beet pulp pellets (by-products), 50,000 tons.
Life cycle description:	Formaldehyde used as a bactericide
Process description:	Sugar beets are delivered to the factory in trucks and are either piled on the ground or dumped directly from the trucks into wet hoppers. The beets float into the factory via a water flume and go through various debris removing processes. After cleaning, the beets are cut into long noodle-like pieces called "cassettes". The cassettes are introduced into the diffuser at one end while water enters the diffuser at the opposite end. The diffuser, about 20 1 in diameter and 200 1 in length, is located in the northwest section of the main building. Approximately 300 tons of beets and a similar volume of water are processed through the diffuser each hour. Inside the diffuser, sugar is extracted from the cassettes via osmosis. The cassettes, then free of most of their sugar, are dried and made into beet pulp pellets. The sugar solution leaves the diffuser in the form of "raw juice". Once removed from the diffuser, the raw juice cycles through various stages of purification, precipitation, pH adjustments (using carbon dioxide gas from the lime kiln), and filtration to remove impurities and other non-sugars. Excess water is removed in the evaporator and the juice becomes thicker. The remaining water is driven off by boiling and then crystallized to a high concentration of sugar called "white massecuite". This massecuite is then centrifuged to remove and separate the sugar crystals from the liquor containing sugar syrups and impurities. The finished sugar is then sifted, packaged, and/or stored prior to shipment. There are other sideline processes not described herein which are used to recover even more of the sugar from the beet. Liquid formaldehyde is stored in a 5,000-gallon tank located on the first floor of the factory underneath the diffuser. It is used inside the diffuser as a bactericide. The quantities of formaldehyde used daily vary with the lactic acid and nitrite levels found in the diffuser and usually range from 0-180 gallons. Formaldehyde is contained in an enclosed system. The controls for the holding tank are located away from the tank in the northeast part of the plant adjacent to the diffuser on the second floor of the slicer deck.

EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability		Metric 1: Methodology	High	The assessment or report uses high quality data from frequently used source (NIOSH HHE).
Domain 2: Representativeness		Metric 2: Geographic Scope	High	The data are from the United States
		Metric 3: Applicability	Uninformative	The report is for an occupational scenario, however, the condition of use is outside of the scope of the risk evaluation due to non-TSCA uses. Formaldehyde is being used as a bactericide, which may be cover under FIFRA and/or under FDA due to use during food manufacturing.
		Metric 4: Temporal Representativeness	Low	The report is more than 20 years old

Parameter	Data			
Life cycle description:	produces garments with designs, numbers, or lettering			
Process description:	Process of silk screening garments has been described here The silk screening operation begins by applying single or multiple colored inks (either water soluble or non-water soluble) to the garment. If the garment requires only one color this in turn means only one screening application. Each additional color requires an additional screening per color. After the garment is screened it is then placed on a conveyor belt which slowly moves it into an ultraviolet heating chamber (temperature equals about 200 degrees Fahrenheit). The garment moves through the heating chamber allowing the inks to catalyze and the garment continues on the conveyor until it is received at the end. It is then placed on a table where the silk screen material completes its drying.

HERO ID:	201729		
Conditions of Use:	Textile Finishing		
EXTRACTION			
Parameter	Data		
Life cycle description:	processing		
Process description:	The bulk material is received from the textile mill on bolts containing approximately 1000 yards of nomex fabric. It is stored wrapped in its shipping cover, which is either paper or plastic, depending on the supplier. Almost half of the building is devoted to storage and cutting. The fabric is cut to order, and the various pieces are stored in bins awaiting assembly by the sewers. The sewing operation is located in the other half of the building, with a small section devoted to the manufacture of other non-nomex uniforms (e.g., service station uniforms). The sewing operators are responsible for making one part of the jacket. The completed piece is then passed on to the assembly people who sew the pieces together, add linings, pockets, collars, sleeves, and buckles until a jacket has been ' completed. The completed jacket is then passed on to another area for quality control checking. Formaldehyde source is indicated from use of melamine formaldehyde resin, a polymer which provides wear and crease resistance, water repellency, increased fabric resistance, and aids in dye fixation.		
Number of sites:	1		
Chemical concentration:	Bulk fabric samples from the site were analyzed by NIOSH and found to have formaldehyde levels between 100 to 600 ppm. Samples from the supplier were found to contained 260-450 ppm via Burlington Industries Standard method and 3.2-10.0 ppm from BEA process. Repeat tests using the BEA process 3 weeks later did not detect formaldhyde, the Burlington method used 2 1/2 month later resulted in similar results as the first test. Dupont conducted their own test with a different method and obtained 0.05-0.13ppm		
Comments:	The report also reports latent formaldehyde amounts found in other NIOSH studies. Those are not included in extracted data as those data will be extracted with the original NIOSH reports.		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	Medium	The report uses two methods (Burlington Industries standard method of latent formalde- hyde, and an alternative method that does not include heating), these are not from fre- quently used sources, but information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the US (KY, USA)
	Metric 3: Applicability	High	The report is for an occupational scenario (incorporation into article- finishing agents in textile) within the scope of the risk evaluation.
	Metric 4: Temporal Representativeness	Low	1983 which is more than 20 years old
	Metric 5: Sample Size	Medium	Distribution of fabric formaldehyde concentrations were characterized by a range, with uncertain statistics. A comparison with other studies was included to help assess how representative the data are.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	It is clear that the information provided was from the site visit, and clearly documents assessment methods.
Domain 4: Variability and Uncertainty

EXTRACTION	
Parameter	Data
Process description:	This facility is engaged in the iron and steel-making industry. An essential feature in the production of iron is the blast furnace where iron ore is melted (reduced) to produce pig iron. The furnace is charged from the top with iron ore, coke, and limestone; hot air is blown in from the bottom, and the carbon monoxide produced from the coke transforms the iron ore into pig iron containing carbon (the limestone acts as a flux). At a temperature of about 1600° C, the pig iron melts and collects at the bottom of the furnace and the limestone combines with impurities to form slag. The furnace is tapped regularly and the pig iron may then be poured into pigs for later use, e. g. in foundries, or into ladles where it is transferred, still molten, to the steelmaking plant. This continuous casting operation utilizes four tapholes which are located around the perimeter of the base of the blast furnace. The four tapholes and trough systems are rotated so that at least two are operational at any time. Iron and slag flow through the tapholes down the trough system to a skimmer box where the slag is separated from the iron, iron flows down one trough system where it is poured into railcars for transport to other steel-making processes. The slag flows down a separate trough to the outside of the building where it cools and is then hauled away. Relining of troughs A clay plug is placed via remote-controlled equipment into one of the four tapholes to seal the tap hole so that the trough systems can be repaired after several days of cooling. Steel coverings over the trough systems are removed by use of remote-controlled overhead cranes; employees are also required to help guide the coverings. The old refractory lining is stripped away using pneumatic chipping equipment, both handheld, and mobile, exposing the brick lining of the trough. Eighty-pound sacks of Narcarb are emptied into the trough and evenly spread over the bottom and pounded. A steel mold is then placed in the trough, sacks of Narcarb are emptied into the space between the sides of the trough, and the mold is pounded with a hand held pneumatic hammer. The steel molds are removed and the trough lining (Narcarb®) is heated and cured for 2 to 4 days. During the heating and curing process, the repairmen are assigned to work in other areas of the blast furnace, stripping and relining one of the other four troughs. After the curing time, the troughs are ready for use and are usable for a period of approximately 10 to 12 days before the relining process is again necessary.

EXTRACTION				
Parameter	Data			
Life cycle description:	The brake block division produces pads for brake shoes.			
Process description:	The sintered metal division produces clutch facing units for use inheavy-duty applications. Clutch facings are composed primarily ofcopper with lesser quantities of other materials (iron, lead, zinc, and graphite). Lead content ranges from 2% to approximately 8% by weight. The powdered raw materials are combined in the mix area. The mixes are transferred to the wafer press area and subsequently compressed into wide, thin, disk-shaped wafers. Pairs of such wafers are sandwiched around single similarly shaped steel disks that have been stamped and/or cut and ground in an adjoining area. These wafer-disk units are sent to the sintering area where they undergo a heating process that metallurgically bonds the wafers to the metal disk. Finally, the clutch facings undergo a series of operations that include curing, grinding, drilling, slotting, and grooving.The brake block division produces pads for brake shoes. Asbestos(chrysotile) , barium, lead, zinc, graphite, and phenol - formaldehyde resin (components vary depending upon the specific formulation) are combined in the mixing area. Subsequently, the mix is transported in an open dumpster to the rotary briquetter, where individual briquettes (blocks of pad material) are formed. An individual briquette is approximately 36 inches long, 7 inches wide, and 1 inch thick. The briquettes are transferred to curing presses, where they are compressed and partially cured. Final curing of the briquettes occurs in curing furnaces. Briquettes then undergo a variety of processing operations including cutting, grinding, and countersink-drilling. The final products are individual brake blocks (pads), approximately 4 inches wide, 6 inches long, and 314 inch thick, that are ready for attachment to the metal portion of brake shoe.

HERO ID:	3970584			
Conditions of Use:	Plastic and Rubber products			
EXTRACTION				
Parameter	Data			
Life cycle description:	The Hoover Company produces vacuum sweepers of various sizes for commercial and home use.			
Process description:	Essentially all of the component parts of the sweepers are manufactured and assembled on-site. This requires several industrial processes, including a foundry operation, injection molding, spray painting, degreasing, plating, extruding, and numerous assembly line operations. The primary operations at the IP include assembly, injection molding, plastic blending and pelletizing, painting, metal fabrication, and plastic extrusion . For injection molding, plastic vacuum sweeper parts are produced in a large open area of the building containing approximately 30 injection molders. Various types of plastics are utilized. In the area machine purges reportedly exposed the machine set-up operators to irritating odors and smoke. Three set-up operators normally work in the injection molding area .

Study Citation:	NIOSH, (1982). Health hazard evaluation report: HETA-81-396-1118. Keebler Company, Cincinnati, Ohio. NIOSH:1-24.			
HERO ID:	4058405			
Conditions of Use:	Baking			
EXTRACTION				
Parameter	Data			
Process description:	Keebler Bakery is composed of two major divisions: baking andpacking. Baking consists of 3 areas; mixing, where the dough isformed; machining, where the dough is shaped into the appropriatesize; and ovening, where the product is baked. Packing consists ofseveral different areas. Those covered during the survey inculde: A-1 and #4 Redi Serve Cracker Lines. The tubs of dough spent several hours in a climate-controlled room at approximately 80°F to allow for yeast fermentation before being transferred to machinery.The dough shaping machines are automatic, requiring one machineoperator for a control panel. The machine operator is also responsible for making hourly checks on the system, i.e. gauging the thickness of the dough.There are 6 ovens in the oven area, and all are fueled by naturalgas. Oven #1 is new (only about 1 year old), and slightly different than the older ovens. Its burners are enclosed for better efficiency, and it uses the circulation of hot air around the crackers to bake them. Older ovens rely on exposing the cracker to radiant heat directly from the burner for baking. The packing section, where crackers are wrapped in various types of containers receives all freshly baked crackers from the ovens.A-1 Redi Serve Cracker Line (receives crackers from oven #1) is composed of 4 machines that automatically feed crackers two at a time into a plastic lining, then cut and heat seals them into individual 2 crackers packages. The cutting and heat sealing is done by a piece of metal called a crimper at about 3000f. Dimethylpolysiloxane oil is automatically dropped ontothe crimper at a rate of 3 drops every 5 minutes to keep theplastic from sticking to the crimper. Number 4 Redi Serve Cracker Line is very similar to A-1 except thatthe machines are much older and the dimethylpolsiloxane is applied manually to the crimper once or twice a day.			
Throughput:	A-1 Redi Serve has been in operation since the beginning of June 1981 and packages, on average, 2200 boxes each containing about 500 two-cracker packages per day.

Study Citation:	NIOSH, (1996). Initial submission: prepublication version of health hazard evaluation of a Unocal Corp urea fertilizer facility, Kenai AK, with cover letter dated 6/13/96.			
HERO ID:	5888126			
Conditions of Use:	Processing into Reactant- Fertilizer			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	The Kenai facility produces approximately 1 million tons of urea and 1 million tons of ammonia per year (11/38)			
Process description:	The Kenai facility produces urea fertilizers through ammonia intermediaries in both prill and granular forms. During the process, a urea formaldehyde concentrate (UF-85) is added to improve the handling characteristics of the urea fertilizer. The UF-85 additive reportedly reacts to form methylenediurea and a combination of urea formaldehyde polymers. (10/38)			
Throughput:	Plant #2 produces from 1250 to 1450 tons of the prill urea per day. Plant #5 typically produces from 1700 to 1800 tons of the granular urea per day. (11/38) Approximately 95% of the domestic urea fertilizer producers condition their urea with a formaldehyde-based additive (ureaforms) and virtually all solid urea producers employ some type of conditioning agent to improve product handling. (12/38)			
Number of sites:	5 plants, 2 of which produce the fertilizer containing formaldehyde. (11/38)			
Chemical concentration:	UF-85 is a liquid mixture containing 60% formaldehyde, 15% water, and 25% urea. (12/38)

Study Citation:	NIOSH, (1983). In-depth industrial hygiene survey report of the arrow shirt company Atlanta, Georgia no: 125.12 (36). 14:B2-14.			
HERO ID:	5908875			
Conditions of Use:	Commercial Use of Fabric, textile, and leather products not covered elsewhere			
EXTRACTION				
Parameter	Data			
Process description:	The Arrow Shirt Company received pre-cured finished fabric from a textile-finishing plant. The dress-shirt fabric was treated at the textile mill with crease-resistant resins and then cured before receipt by Arrow Shirt. Treated fabrics give off various levels of residual formaldehyde, depending upon the type of fabric, type of resin system, and type of manufacturing treatment the shirt requires. The fabric in use during this survey had been treated with a resin produced by Sun Chemical Company called dimethyl-dihydrodi-ethylene-urea. The Atlanta plant received pre-cut shirt parts in lot sizes of 200 dozen each from an Arrow pattern cutting plant. Each shipment of shirt parts was checked for quantity and quality and then scheduled for production. Distinct steps in the manufacture of dress shirts at the Atlanta plant include the following: (1) Collar and Cuff: A lining is fused (with heat) to the collar and cuff fabric parts. The collar and cuff are then turned right side out and pressed, and the collars are stitched to a collar band. Buttonholes and buttons are added to the cuffs and collars. (2) Yoke and Back: The yoke and back of the shirt are sewn together. (3) Fronts (Joining): The centerplate is sewn onto the shirt fronts, and the buttonholes are then sewn into the centerplate. (4) Assembly Operation: The collars are sewn to the yoke and front after joining. (5) Cuff and Sleeve: The cuffs are sewn onto the sleeves after the sleeves are added to the body of the shirt. (6) Spot Removal: Dry-cleaning agents are used to remove spots from the fabric of shirts. (7) Finishing: The completed shirts are pressed on an apparel press, buttoned, folded, and boxed or bagged for shipping.			
Throughput:	Approximately 1600 dozen shirts were scheduled for completion each day. The residence time of the fabric in the plant was usually no longer than 4 days.

HERO ID:	8610851			
Conditions of Use:	Textile Finishing			
EXTRACTION				
Parameter	Data			
Process description:	The plant process begins with the unloading of loom-state fabric (gray goods) obtained from several countries. These include the United States, China, Japan, India, and Taiwan . Rolls of fabric are sewn together into a continuous length and mercerized in the greige department. Mercerizing is a continuous process in which fabric is treated under tension with hot caustic soda to makeit stronger and more receptive to dyes. Following this, residual starch is removed by enzyme digestion. The fabric is then steamed, acid dipped, neutralized, washed, and bleached with sodium hypochlorite and hydrogen peroxide in the white department. It is then dried in frames at 300 - 4000 c. In the screen print department polyester fabric is disperse-dyed a solid color and then screen-or roller-printed. The dyestuffs may contain one or more dyes, a dye carrier, and antimigration and antifoaming agents. These are weighed and mixed by an operator on an elevated mixing platform and emptied into a vat. After dyeing and printing, the fabric is pre-dried under infrared lamps and then passed into a hot house tenter frame which holds the fabric at a desired width to prevent shrinking. Selected fabrics and patterns may be subjected to an "ageing" process, which involves treatment with acetic and formic acid. After ageing, the fabric is cleaned in a soaping process, which improves the absorbency of the fibers prior to chemical finishing. In the chemical finishing process the cloth is treated with urea-formaldehyde resins, softeners and wetting agents. These give permanent press, durability, dimensional stability, spot resistance and water repellant qualities to the cloth. Following this the surface of the cloth may be finished (e.g. knapped) before being shipped to clothing manufacturers. (The fabrics used arepretreated with flame retardant when purchased.)

EXTRACTION				
Parameter	Data			
Process description:	Friday and 2 hours on Sunday. On Friday, two operators pump concentrated EP liquid from a 55 gallon drum into a closed mixing tank where 35 gallons of EP liquid is mixed with 165 gallons of water. An overhead piping system then allows for each of the 10 extruders to be sequentially filled with approximately 20 gallons of diluted EP liquid. As each extruder is filled, an operator positions a 4-wheeled, plastic cart at the exit orifice to catch excess EP liquid. The extruder is then plugged and the process continues at the next extruder in line until all units are filled. The plastic cart which now contains a mixture of meal and EP liquid is moved to a small washroom where it is emptied into a floor drain by turning it on its side. On Sunday evening, two extruder operators spend approximately 2 hours draining the extruders in preparation for the Monday production run. This process begins by preheating the extruders with 2470F steam. Then, each extruder is unplugged and the contents are drained into a plastic cart as it is moved down the line. After all units are empty, the extruders and the floor of the extruder room are hosed down with hot water to remove residual EP Liquid and meal.

EXTRACTION				
Parameter	Data			
Process description:	Parisons are pushed, end-to-end, from a feed hopper through a tube to a gravity feeder where they are dropped onto vertically projecting pins which are part of a continuously moving carrier chain. The carrier chain conveys the parisons through the electrically fired conditioning oven as their temperature is raised to orientation temperature. At the oven exit the parisons are removed vertically from the carrier chain by picker fingers, transported horizontally to the molding station and with a downward vertical motion placed into the molding station. Prior to insertion of each set of parisons the molds are sprayed automatically with a dimethyl siloxane polymer used to ensure proper mold release. In the molding station a mandrel (inside metal collar) rises into the interior of the parison as a pair of thread forming dies compress the lower end of the parison against the mandrel. This action forms the completed bottle neck and anchors the parison . The picker finger rise rapidly, stretching the parison, and the mold halves close on the stretched parisons. Air is blown through the mandrel into the parison conforming the plastic to the shape of the molds. The plastic is cooled in the molds, the molds and dies open, and the bottle is ejected from the machine by a pulse of air. The bottles are conveyed from the module by a chute to a conveyor belt and over to a packing area where they are flame treated and boxed. (3/14)

Process description:	Dry sand at 90 degrees F and binders, (phenol formaldehyde resin, methylene bisphenol diisocyanate catalyst, and a aromatic hydrocarbon solvent) are automatically fed into the mixers, and dropped into wooden forms for hardening. These forms are transferred to a rollover machine which removes the molds. Each rollover machine is operated by one employee. Workers, called "mold toppers" manually fit each mold with a top or core and apply foundry paste to seal the mold. All newly formed molds are then loaded into metal containers called "cans" which are packed with loose sand for support and to slow refractory cooling after the pour. Cans are automatically moved by crane into the furnace area where molten silica is poured into the sand mold. The furnace operator is inside a climate control booth during the pour. Immediately after the pour, cans are moved by crane to the extra "hot hole" department of the furnace area where the pour funnels are manually removed. The cans are then transferred by crane to the "annealing building" where they are cooled for 4 days to 2 weeks. After cooling, cans are taken to a shake out area where hardened refractory is removed from the can and sent through the finishing department to be prepared for shipment. (5/27)

EXTRACTION				
Parameter	Data			
Process description:	Facility #1: At the time of the initial environmental survey, a machine (Lixivitron, United Medical Products) was utilized for automatic cleaning and disinfecting of the units. Use of the machine was discontinued prior to the follow-up environmental survey. A manual procedure was then utilized in which cleaning and disinfecting were carried out over a large shallow sink by a re-use technician. Following cleaning and volumetric testing, a vacuum aspirator connected to the sink faucet was used to draw a 3% formaldehyde solution into the kidney unit. The unit was then capped and placed on a cart for storage. A maintenance technician also spent time in the area. This employee was responsible for routine repairs of the dialysis units. Following each repair, a 3% formaldehyde solution was passed through the machine’s network of tubing.Facility #2: Cleaning and disinfecting of the artificial kidneys at this facility were also carried out manually over a large shallow sink. At the time of the initial environmental survey, the fluid from the aspirator was channeled directly into the drain using a long section of tubing. During the follow-up environmental survey, the tube had been removed and the fluid from the aspirator flowed into the sink before reaching the drain.Facility #3: The cleaning and disinfecting process was conducted in a manner similar to the other facilities except that a shorter and deeper sink was utilized for cleaning .			
Chemical concentration:	Artificial kidney units are cleaned and disinfected with a 3% formaldehyde solution.

EXTRACTION			
Parameter	Data		
Process description:	Shellcore: There are two shell core work stations in the foundry. One operator operates one pneumatic shell core machine in the northeast corner of the plant. Shell cores are formed when the sand, precoated with a thermosetting resin binder (Faskure), is placed in a gas-fired core box at 550-600°F for 6-10 minutes. After the polymerized shell cores are manually removed from the machine they are placed on a nearby worktable to cool and off-gas for 2-3 minutes. Two, twenty-four inch pedestal fans, positioned about one foot above the work table, aid in dispersing any emissions from the cores into surrounding work areas. On an as needed basis, a Bink’s hand-held compressed air atomizing gun is used to disperse a solvent based parting compound on the core box to help prevent the sand from sticking to the mold pattern. Somewhat smaller shell cores are made at another shell core operation positioned in the northwest corner of the plant where one employee operates one or two shell core machines. The working conditions, production materials, and equipment used are essentially the same in both shell core manufacturing operations. Phenolic Urethane: A phenolic urethane, no-bake Isocure system is used at two work stations in the northcentral part of the foundry: U-180 machine and bench Isocure, each with one operator. The process involves three parts: part I, a liquid phenolic resin; part II, a liquid isocyanate (methylene bisphenyl isocyanate, MDI); and part III, the catalyst, an amine gas (dimethylethylamine). Parts I and II are manually added to and mixed in equal amounts along with sand in a 500 (lb) capacity muller. Sand is gravity fed to the muller from one of two storage silos. Mixed sand from the muller is transported to hoppers above the core machines and is either pneumatically forced or gravity fed into the corebox. Once in the corebox mold, the sand mixture is gassed with varying amounts of the amine catalyst for about 1-10 seconds depending upon the size of the core. The U-18C and bench Isocure® operations are quite similar with the bench Isocure processes being a little less automated. Both machines, U-180 and bench Isocure are equipped with local exhaust systems to aid in purging excess amine gas from the cores. Once every 20 to 25 cores made, a solvent-based mold release agent is dispersed into both core machine mold boxes via a hand-held can with a mouth piece so that the employee must blow into the can in order to aerosolize the release agent. The same mold release agent and method of application are used in the bench coremaking operations. Bench Coremaking: Two to three employees work at the bench coremaking processes stationed in the northwest corner of the foundry. Initially, the components of the bench sand, including varying amounts of an alkyd core oil, cereal-binder (ground corn), kerosene, iron oxide, phenolic coated sand, and water are mixed in a 400 (lb) capacity sand muller for about 20 minutes. The sand mixture is transferred via wheel barrel to one or both of the bench coremaking worktables and the one blow bench machine operation. The bench coremaker uses several hand tools such as mallets, hammers, trowels, and metal “strike-off” bars to hand pack the sand into the core pattern. Blow bench procedures are the same except that the sand mixture is pneumatically forced into the core pattern cavity. Finished cores are placed on transite boards and cured in gas-fired ovens at 420°F for nearly 4 hours on second shift. Cured cores from each coremaking department are sent to the foundry mold floor. (pdf pg. 4-6)		
Comments:	Report only monitored for formaldehyde for the shell core processes, phenolic urethane process, but not the bench coremaking (pdf pg. 6)

Parameter	Data			
Process description:	In the padding process, textile scraps are combined with a phenolic resin at 300-500 degrees F to form a green phenolic pad or are combined with latex to form a gray resinated pad. Phenolic pads are molded to fit the cars’ shape in a hot press. In the asphalt process, a rolling machine forms a thin layer of asphalt which is then sandwiched between two sheets of polyethylene plastic. In the rubber process, a sheet of rubber is combined with a phenolic pad and heated to 500-550 degrees F in a curing oven. The product is sprayed with cold water before being cold molded into its final shape. (4/18)

HERO ID:	8683475		
Conditions of Use:	Personal Care Products		
EXTRACTION			
Parameter	Data		
Process description:	The nail salon technicians at these salons provided a variety of services:Acrylic nails: application, fill, and removal. Standard acrylic nails were created when acrylic monomer liquid was mixed with acrylic polymer powders and applied to the natural nail (with or without a nail extension). The acrylic was shaped using a small brush when still curing and shaped further using a handheld powered rotary filing tool to make the final nail shape after the acrylic had hardened. Then the nail was cleaned and painted using standard or gel polish. The dip acrylic nail manicure involved alternating layers of cyanoacrylate nail glue and finely milled methacrylate polymer powder on the natural nail with an extension. The nail was either dipped into or sprinkled with the powder. These layers were repeated several times to create a strong acrylic nail. The copolymer typically was pigmented and the nail did not need further colored polish.Manicures and pedicures: during manicures and pedicures, technicians used hand tools to trim and shape the natural nail. Products used during this service included nail polish remover, disinfectants, rubbing alcohol, lotions and moisturizers, callus remover or softener, colored nail polishes, and clear coats. Gel and shellac manicures and pedicures involved polish cured using ultraviolet light into a hard, shiny coating. This coating was generally removed by soaking in acetone.Technicians at three of the salons (B, C, and D) also provided waxing hair removal services.		
Number of sites:	4 Salons were studied.		
Chemical concentration:	Formaldehyde was found in concentrations of 0.128%(mean) in used nail polish and 0.0474%(mean) in unused nail polish.

HERO ID:	8684536			
Conditions of Use:	Plastic and resin manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The manufacturing process involves the extrusion of film, flexographic printing, and bag making. The facility operates 24 hours per day using a variety of shift schedules that generally differ between departments. Polyethylene and other ingredients are extruded together (forced under high pressure through a hot, metal die) continuously, and the resulting plastic film proceeds through an array of rollers to a cutter and onto large rollers or spools. This process produces a variety of chemicals such as alcohols, acetates, aliphatic hydrocarbons, and ozone, during the melting of the polyethylene pellets. The extrusion department operates 24 hours a day, for 7 days a week. Mat boards are hardened in mold-making machines using a heated process. Once hardened, the molds can be used to make rubber printing plates, which are then affixed to the rollers of printing presses and used to print labels onto plastic films used in packaging. A variety of solvents are used in the printing process, including, alcohols, solvent blends, and solvent-based inks. There are 18 flexographic presses, operating 24 hours a day, seven days a week. The printing department employs approximately 230 people, who are organized into four crews. Plastic films are heat-sealed on 62 automated bag machines to make plastic bags for packaging. The thermal sealing and cutting of the bags releases smoke that contain formaldehyde and acrolein, various other organic vapors and particulates. The bag machines are equipped with local exhaust ventilation. The bag department employs 170 people, who work 5 days per week on three 8-hourshifts.			
Throughput:	The bag department consisted of approximately 60bag machines that could manufacture bags at a rateof 300-500 bags a minute

EXTRACTION				
Parameter		Data		
Process description:		Different adhesives are used in the bonding of the boards depending on the characteristics required of the finished product. The synthetic adhesives used by the suppliers to the facility are urea-formaldehyde and principally phenol-formaldehyde resin systems. The fabrication process involves a multiplicity of different types of woodworking machinery common to the industry. The process begins in the saw-sanding department where the boards are cut to serviceable sizes. This involves a multi-blade rip saw used for cutting the boards into strips of different widths which are cut into a multiplicity of segments of various lengths by cross-cut saws. Belt, drum and pneumatic sanders are employed where needed for caliper control or surface smoothness. The boards proceed to the fabrication department where they are formed in the woodworking area and/or cut in the punch press area. The boards are formed by shapers, routers, planars, and other miscellaneous woodworking machinery. The punch presses are used to obtain precision cut hardboard parts. (2-3/27)

EXTRACTION	
Parameter	Data
Process description:	The cloth is received in the White Department from the bleach plant in a wet condition although portions of the cloth may have dried out. The cloth is first run over a roller and through a wet box to obtain fairly uniform moisture throughout the cloth. The wet cloth is then run over a series of steam heated dryer cans which predry the cloth to a moisture content of 15-18%. The cloth then travels through a series of three hot frames which are heated by natural gas to a temperature of 300-400°F. which completes the drying. For polyester and polyester blends it is necessary to heat set the fabric to fix the width of the cloth which is very critical for the printing operation which is to follow. At the offtake end the dried/heat set fabric is then wound onto a core to form a roll weighing several thousand pounds (approximately 3-4 feet in diameter). (3/32)

HERO ID:	8688557		
Conditions of Use:	Plastic material and resin manufacturing		
EXTRACTION			
Parameter	Data		
Process description:	The operation of concern involves the production of an automobile dashboard part in molding room #2 (dimensions of about 100 by 20 feet with a 15-foot ceiling), at Press #22. Approximately 1 ,500 to 2,000 dashboard units were produced each day (as observed during the periods of this evaluation). A total of four employees per shift, three shifts per day are involved in the immediate area of Press #22. The backside operator places a piece of wood-grained vinyl plastic sheet on a 11 vacu-form11 machine. The vacu-form heats (infra-red lamps) the vinyl plastic sheet and forms (by vacuum under the sheet) the dashboard features. This formed sheet is placed into the face of the mold with the aid of a "static electricity wand. " Zinc stearate is applied to the mold face as a release aid. An acrylonitrile-butadiene-polystyrene copolymer (ABS material) is injection molded to this vinyl sheet to give the dashboard rigidity. The ABS material which is used~ this operation is commonly a mixture of 11 virgin 11 ABS (Monsanto Lustran, and reground scrap ABS materials. These reground materials are commonly the rejected dashboard parts (containing PVC and ABS material), and other non-ABS materials. The front side operator then removes the dashboard piece and trims off unwanted portions. A 11 cut-off11 operator performs further trimming adjacent to Press #22. Another employee relieves the front and back operators during lunch and coffee breaks.		
Throughput:	1,500 to 2,000 dashboard units were produced each day.

Study Citation:	NIOSH, (1974). Health hazard evaluation determination: Osborne Photographic Laboratories, Inc..			
HERO ID:	8688937			
Conditions of Use:	Photographic Supplies			
EXTRACTION				
Parameter	Data			
Process description:	Osborne Photographic Laboratories, Inc. processes and develops color, black and white films, and prints. With the exception of the hand printing operation most of the developing and printing operations are automatic. The chemical mix facility located in a loft and the hand printing process were the operations evaluated. Twenty-five gallon stock photographic solutions (commonly referred to as a "fix " an "stop-fix" solutions) are prepared in the loft on an as needed basis, usually once a week. The stop-fix solution container is partly filled with water; part A, a dry chemical, is added and mixed with an electric driven stirrer-agitator until the chemical is dissolved. One gallon of acetic acid is then added and mixed. The procedure for preparing "fix" solution is identical to "stop-fix" solution except that Part A is a different dry chemical and 1 quart of formaldehyde is substituted for the gallon of acetic acid. During the addition of acetic acid or formaldehyde the worker holds the gallon or quart container as it is poured into the partly filled stock solution containers. The dilution proportions of the work solutions are 20:1 and 30:1 for the "fix" and "stop-fix" solutions respectively. Three employees are assigned the responsibility of preparing batch stock solutions in addition to other duties. The time consumed in preparing a batch of solution varies from 10-15 minutes. While preparing the stock solution the worker usually remains in the loft until the stock solution is properly prepared. It is not necessary that he remain atop the containers while the solution is being mixed. Space is available where the employee can position himself away from the container if necessary. It is only during addition of chemicals that the worker is atop the container to which the chemicals are added. A total of 5 stock solution containers are located in the loft. Two employees are engaged in black and white hand printing process in the dark room. Stop and stop-fix solutions used in the hand printing process are dilute stock solutions. Rubber gloves are available to the employees working in the black and white handprint.			
Chemical concentration:	The water/formaldehyde dilution ratios for the "fix" and "stop-fix" solutions are 20:1 and 30:1 respectively.

EXTRACTION				
Parameter	Data			
Process description:	The braided hose department employing approximately 70 peopleoccupies three floors of a brick building with wooden floors. Identical solutions are used on each floor, with frequent changes in the formulations. The process consists of applying a braided polyester thread reinforcement to various types of unvulcanized rubber hose. Braiding machines weave the thread around the hose and most of the work force are engaged in operating these machines. The threads are passed through dip tanks containing the previously-mentioned chemicals prior to winding on spools and utilization by the braider. The composition of these dips is varied depending upon the characteristics desired in the finished hose.Approximately 2,200 different types of hose are produced and usually in relatively small lots. This makes the task of identifying the exact composition of an individual dip very difficult, since hose lots are identified by serial number; and these are seldom remembered by employees.Exposure to the employees would result from vaporization of chemicals coming from the fibers that have been pre-treated. The chemical containers, where the fibers pass through and are coated with the numerous formulations, are closed and are located on the floor. Any exposure coming from the tanks or from the treated fibers would have been collected on the breathing zone samples of the workers involved, since these workers have to replenish thesupply of-solutions in the chemical containers.

HERO ID:	8728028			
Conditions of Use:	Adhesives and sealant chemicals in wood product manufacturing			
EXTRACTION				
Parameter	Data			
Life cycle description:	Produces veneers and furniture			
Process description:	Veneered panel consist of a core with a face and a back veneer glued to each side (additional pairs of plies may be added). Hot-press process- heat metal plates which apply the pressure and heat the glue. RF-procees- uses radio-frequency radiation to generate heat, the hydraulic press only applies pressure. Cold-press processes apply pressure while the boards are maintained between 60 deg and 100 deg F, this require much longer cure times. (5/22)			
Throughput:	14,000 ft2 per day for hot-press production, average daily glue-line square footage was approximately 48,000 ft2; 10% of this was produced on the RF press, less than 20% of panels are produced via cold-press (5/22)			
Number of sites:	Studied 1 site

Study Citation:	NIOSH, (1983). Preliminary survey report: Control technology for formaldehyde emissions at Drexel Heritage Plant 60, Morganton, North Carolina.			
HERO ID:	8728030			
Conditions of Use:	Adhesives and sealant chemicals in wood product manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	The veneers are received as thin strips bundled together. The strips are pressed, trimmed, and joined into sheets, which are cut to the proper size. The panels are prepared for pressing by passing them through a glue-spreader and stacking layers on top of each other repeatedly. The panels are placed on a conveyor belt, and heat and pressure are applied for 2-3 minutes. After the pressed panels have been inspected, they are stacked and moved to the loading dock. (6/10)			
Throughput:	The normal production level averages between 20,000 and 30,000 square feet of panels per day. (4/10)			
Chemical concentration:	Glue contains almost 90% urea formaldehyde resin. (7/10)

HERO ID:	8728035		
Conditions of Use:	Adhesives and sealant chemicals in wood product manufacturing		
EXTRACTION			
Parameter	Data		
Life cycle description:	Formaldehyde is used in urea-formaldehyde adhesives for veneered panels and then emitted during the hot-pressing procedures.		
Process description:	The simplest veneered panel consists of three plies, a face and a back veneer glued to each side of a core. Additional plies may be added to make a panel which is stronger and more stable dimensionally. An established way to achieve a high rate of production is to reduce the glue-curing time by heating the glue while pressure is being applied to the panels. One way to do this is to heat the metal plates which apply the pressure, generally referred to as a "hot-press" process. Another way is to generate heat in the glue-line with radio-frequency (R/F) radiation in much the same way that food is cooked in a microwave oven. "Cold-press" processes, those for which pressure is applied while the boards—and glue—are maintained between 60 and 100°F, require much longer periods of time for the glue to cure. For most applications, the glue which currently provides the best performance for the least cost is a urea-formaldehyde (U/F) resin adhesive. The core may be a sheet of veneer, particleboard ("chip-core") or fiberboard, or a piece of edge-glued solid-wood "lumber-core". Almost all particleboard and fiberboard are made with formaldehyde resin binders, and a formaldehyde resin glue may be used to assemble lumber-core. To improve the appearance of a panel, the core may be "banded" with solid wood edges prior to veneering. Here again, the adhesive may contain formaldehyde. A variety of hardwoods and softwoods, including oak, walnut, poplar, and pine, are used for veneer stock. Some plastic laminates are being used in certain products; usually these panels are cold-pressed. The veneers are received in flitch form, thin strips bundled together as they were cut from the log. The veneer flitches are pressed, trimmed, and joined into sheets, which are then cut to the proper size for the panel being produced. The large panels of particleboard and fiberboard are cut into pieces of the appropriate nominal size. Hoosier Panel makes its own lumber-core, using its facilities for kiln-drying green lumber, surfacing the rough lumber, cutting the boards into thin strips, and edge-gluing these together into a continuous length which is then cut into pieces of the necessary size for core stock. The cores are then banded, if necessary, and trimmed to the desired size. Hot-press veneering is accomplished on one of three steam-heated platen presses, operated at around 250°F. There are two ten-opening presses, one five-opening press, and two glue spreaders located in the glue room. The decision of how many presses and spreaders to run is primarily determined by workload. Four workers are required to operate a press: two loaders and two unloaders. The procedures are intensively manual. As is typical for this type of press, processing the boards through the press is facilitated by sandwiching the boards to be pressed between metal caul plates.		
Throughput:	The normal production level averages between 20,000 and 30,000 square feet of panels per day.		
Chemical concentration:	Perkins L-100 is a high solids (63-65 percent) urea resin with no more than 3 percent free formaldehyde.

HERO ID:	8728041			
Conditions of Use:	Finishing agents in textiles, apparel, and leather manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	During the finishing process, resins containing formaldehyde are combined with catalysts and cured in ovens at high temperatures to form the permanent press treatment of fabrics. Several varieties of resins and catalysts are used in the textiles industry. Their application depends to a large extent on the effects desired in the finished product. (11/26, in depth description from 10-13)The textiles industry uses formaldehyde resins and ionic chloride containing catalysts in permanent press treatment of fabrics. Sampling was deemed necessary at Burlington Industries finishing plants because they were using resins of high free formaldehyde content (carbamates) together with magnesium chloride catalysts. The combination was thought to enhance the formation of BCME as opposed to plants which use low free formaldehyde resins and zinc nitrate catalysts (or some other catalyst of low chlorides content). (5/26)

HERO ID:	5957490				
Conditions of Use:	Manufacturing fiberboards				
EXTRACTION					
Parameter	Data				
Process description:	For the manufacturing of ultra-low density fiberboards (ULDFs), fibers of 12% moisture content based on dry weight were weighted and put into a blender whose top had a small hole. To treat the surface of the fibers, unsaturated polyester resin (UPR), toluene di-isocyanate (TDI) and methyl ethyl ketone peroxide (MEKP) were sprayed in sequence into the blender by using a spray gun. UPR and TDI consumption was 10–14 and 0.5–1.5% of oven-dried fiber weight, respectively. The amount of crosslinking initiator MEKP was 3% of that of UPR in weight. After spraying, powdered paraffin, equal to 0.8% of oven-dry fibers weight, was added to enhance waterproofness of the fibers. For each sample of ULDFs, treated fibers were weighted to correspond to a target density and transferred into mats. The mats then underwent a prepress stage, followed by hot-pressing to form the boards of 370 × 370 × 10 mm3. During hot-pressing, the temperature of the press plates was set to 200 deg C, and the applied load adjusted to result in a pressure on the mat of 500 Pa. The boards obtained were stacked together for 48 h to let them fully cure and be conditioned to equilibrium moisture content in the test-lab. Afterwards, the boards were trimmed into uniform size, as a final preparation before testing mechanical and physical properties.

EXTRACTION				
Parameter	Data			
Process description:	80% produced by catalytic oxidation of ethylene in aqueous solution. Two quite different processes are used. In one, a mixture of methanol and oxygen is passed over a silver catalyst. In the other process, a mixture of methanol and air is passed over a catalyst consisting of molybdenum and iron oxides.			
Throughput:	'9 billion lbs/yr of the 37-50% aqueous solution or 3.3 billion lbs on an anhydrous basis is prepared (in 1978); 65% of the formaldehyde produces is used in the same plant in which it is produced (pg 33 of 384). 50% - production of urea-formaldehyde and phenol-formaldehyde resins. 20-25% - other resins or high polymers (e.g., polyacetals, melamine resins, alkyd resins) also used to produce hexamethylenetetramine, pyridine			
Number of sites:	16 companies.			
Comments:	Plant capacities vary widely from about 14 to 600 million lb/yr. Three companies (Celanese, Borden and DuPont) have over 50% of our national capacity. Most formaldehyde is stored and transported as aquous solutions containing 37-50% formaldehyde and 1-15% methanol (page 33 of 384). Costs fir transportation tend to be high because water and methanol also are needed to be transported. Several large plants are near lumber plants in the South and the far West.

Study Citation:	OECD, (2015). Emission scenario document on use of adhesives.			
HERO ID:	3833136			
Conditions of Use:	Use of Adhesives			
EXTRACTION				
Parameter	Data			
Process description:	Adhesives are formulated by mixing together volatile and non-volatile chemical components, such as binders, plasticizers, and solvents in sealed, unsealed, or heated processes. The specific formulation process, which is outside the scope of this ESD, depends on the type of adhesive being produced. This ESD assumes that the formulation step occurs at a separate site from the application step. Additional information on the formulation of adhesives, including methodologies to estimate environmental releases and occupational exposures, can be found in the Emission Scenario Document on Adhesive Formulation (OECD, 2009).The main components of adhesive products typically include elastomers or adhesive polymers, tackifiers, fillers, and solvents; however, other components may include plasticizers, stabilizers, viscosity control agents, preservatives, surfactants, and antioxidants.The reference includes a comprehensive discussion of adhesive applications, but some of this discussion may not be relevant as the only adhesive of interest is Phenol-Formaldehyde resins, which may require specific application methods as it is a reactive using polycondensation.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	OECD report based on EPA study and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The report is from the United States
	Metric 3:	Applicability	Medium	The report is for an occupational scenario (use of adhesives) within the scope of the risk evaluation, but information is general for the use scenario and not necessarily specific to formaldehyde.
	Metric 4:	Temporal Representativeness	High	The report is generally no more than 10 years old (2015).
	Metric 5:	Sample Size	N/A	No sample data were extracted.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	This report aggregates all of the information such that it is not possible to differentiate what processes and application techniques apply to Formaldehyde.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	High	The report addresses variability and uncertainty in the results.

Study Citation:	OECD, (2002). SIDS Initial Assessment Report: Formaldehyde (CAS no: 50-00-0).		
HERO ID:	5348397		
Conditions of Use:	Production and processing		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	The global production of formaldehyde in 1999 is estimated to be 5 – 6 million (metric) tons (Asia: 1–1.5 million tons, North America: 1-1.5 million tons, Western Europe: 2-2.5 million tons).Page 9 of 395		
Life cycle description:	Formaldehyde is mainly used as an intermediate in the chemical industry for the production of condensed resins for the wood, paper and textile processing industries (approx. 40% urea-formaldehyde resins, 10% phenol-formaldehyde resins, 10% polyacetal resins and 5% melamin-formaldehyde resins). Formaldehyde is also used in the synthesis of methylene dianiline (MDA), diphenylmethane diisocyanate (MDI), hexamethylenetetraamine (HTMA), trimethylol propane and neopentylglycol (in total approx. 25%), pentaerythritol (5%) andacetylenic agents (5%) (BASF-SRI Consulting, Jan. 2000).		
Chemical concentration:	The sales product in aqueous solution contains in general 35 – 55 % formaldehyde. The 49 - 49.3 % sales solution of BASF product of formaldehyde contains the following impurities: Methanol: 0.5 – 2 % w/w, Formic acid: about 0.3 % w/w, Iron: < 0.0001 - % w/w (page 7)

HERO ID:	5943040			
Conditions of Use:	Use of Floor coverings			
EXTRACTION				
Parameter	Data			
Process description:	”The MDF core of Lumber Liquidators’ laminate flooring is manufactured with urea-formaldehyde (UF) resins. These resins release formaldehyde from the core as free formaldehyde that exists in the MDF following manufacture, as well as formaldehyde created from hydrolysis of the UF resin by water vapor. The free formaldehyde results in initially higher emission rates following installation, while hydrolysis caused by indoor relative humidity is responsible for the long-term emission rates. The top (wear) layer of laminate flooring typically consists of a melamine resin...” (pg 2)

Overall Quality Determination		High		

Study Citation:	Oh, Y. S., Lee, J. K. (2004). Evaluation of Korean softwood plywood bonded with urea-formaldehyde resin adhesive. Forest Products Journal 54(2):77-80.			
HERO ID:	5945093			
Conditions of Use:	Processing: Wood Product Resin Manufacturing			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	”In 2000, the worldwide production/consumption of wood-based panels (such as particleboard, medium density fiberboard, oriented strandboard, and veneer board products) was 171 million m3, with plywood accounting for about 32 percent (FAQ 2002). In 2001, in North America, the quantity of construction and industrial plywood produced by 92 plywood mills was 15.4 million m3 (17.4 billion ft. 2 , 3/8 in. basis), accounting for 44 percent of the total wood composites produced in North America (Panel World 2002). During approximately the same time period, more than 1 million m3 of hardwood and decorative plywood were bonded in North America, mainly with urea-formaldehyde (UF) adhesives and principally for interior applications (Sellers 1999)” (1/4)			
Process description:	””””A UF resin was synthesized in a 4-L glass reactor to determine the best conditions to control the exothermic reaction. . . Rotary-cut Korean softwood veneers were supplied by a commercial plywood manufacturing industry in Korea. The veneer was 2.1 mm in thickness, 4 to 6 percent moisture content (MC). The veneers were checked for wood density and pH... The adhesive spread was applied with a roller coater at a rate of 171 g/m2, single glueline basis. The total assembly time, which includes the time from first adhesive application until hot-pressing, was 30 minutes. A total of nine panels were hot-pressed at 120””C for 4 minutes. The prepress and hotpress pressures were 1034 kPa (150 psi) and 1379 kPa (200 psi), respectively.”” (2/4)”			
Chemical concentration:	The UF resin used in this study was made with 16.19 moles of urea, 18.62 moles of formaldehyde, and 52.9 moles of water. It contained 0.52% free formaldehyde. (2/4)			
Comments:	Mainly process description. The production volume information relates to wood-based panels, some of which is not specific to Formaldehyde. The concentration information is just specifying the concentration of formaldehyde used to produce the resin.

Process description:	Paper matte is fed from large rolls through a series of accumulation loops before entering the asphalt saturator. The large rolls are continuous since they are attached together via an operation called splicing. In the saturator, hot petroleum liquid asphalt which has been heated to approximately 400°F is applied to the matte as it passes through another series of loops. When it leaves the saturator, the matte has been completely saturated with asphalt. The saturated matte then passes through a baffle of liquid asphalt which has been thickened. This bath and baffle system is known as the coater. When fibrous glass matte is run on the production line, the saturator is not used, and the matte goes directly through the coater. As either type of matte leaves the coater, granules of the desired color are dropped on the top side of the matte and pressed into the still hot asphalt with a roller ("pressroll area") . Additionally, a mixture of sand and talc is placed on the backside of the matte to pre vent sticking and three thin strips of polyester film are applied. The material then passes through a water spray and another series of cooling and accumulation loops ("cooling section"). An intermittent strip of liquid asphalt is applied to the shingle at the sealamatic resin strips applicator as it leaves the cooling loops and proceeds to the final steps (cutting, stacking, wrapping, and storage). Process description:	Formaldehyde is one of the major components present in phenolic alkaline and furanic resins, which are the most widely used binders of the silica sand to produce the molds and cores. Sand molding is one of the most versatile metal-forming processes, providing tremendous freedom of design in terms of size, shape, and product quality. Molds and cores used in foundries for the manufacture of metal objects are formed by agglomeration of large quantities of sands with binders. The mold and core are destroyed after the production of a single metallic piece.

EXTRACTION	
Parameter	Data
Production, import, or use volume:	Annual production data from Chemical and Engineering News 1989 but is for PV of 1988. PV of formaldehyde: 3.37 x 10 ⁶ tons.
Process description:	List of several processes provided in Table 3 for various waste minimization alternatives in the chemical industry and in the article several are described. Lower-temperature processing - Lower-pressure (and therefore lower temperature) operation of distillations and other conventional separations can reduce losses from polymerization and degradation of monomers, biological products, and other heat -sensitive materials, with less inhibitors. Lower- temperature coolants on process overheads can help reduce losses of volatiles to vent systems discharging to flares. Replacing cooling water with chilled water can reduce byproducts related to reactions on surfaces in jacket- or coil-cooled reactors. Cool storage can provide the capacity to condense and recycle upset releases of volatiles that might otherwise be sent to flares. Such releases often overwhelm vent refrigeration systems without cool storage that are typically sized for normal vent flows. In-plant conversion of waste streams to clean fuels or feeds - Many organic chemical processes produce tars that are separated and sent to hazardous waste disposal or to in-plant incinerators. Some of these streams contain significant inorganic contents. Pressurized gasification can achieve complete conversion at a higher temperature than incineration with oxygen, and the syngas is cleaned in a pres ^r - surized process to obtain a clean fuel or chemical feedstock gas. No permits are required for their convertors per se, but only for their ultimate combustor, if the gas is used for fuel. Extensive pilot testing of waste gasification and leachability testing of the inorganic slag residues would be required before gasification of any particular type of residue could be commercialized. Avoidance of extraneous water streams introduced to chemical processes - In many chemical and refinery processes, steam jet evacuators or ejectors are used to create process vacuum conditions. Direct steam stripping also is used to make separations of organics in many processes. These operations result in contaminated waste streams that are typically treated in bioponds or concentrated and then incinerated. It may be better to reduce losses by eliminating this water, which is used solely to perform a physical function (such as to create a vacuum, improve separation coefficients in distillation, etc.). A mechanical vacuum system offers an alternative to steam jets, which do not create volumes of contaminated water as a by-product. Heat pumps can be used to recycle the contaminated condensates from the overheads of steam strippers. Selective separation by membranes - Membranes offer an attractive alternative to distillation as a means of separating products at much lower energy costs and superior means of product recovery. Current polymeric membranes suffer from attack by solvents and are limited by temperature to a narrow operating range. The membranes are subject to clogging and cannot be readily cledned. Ceramic and metallic membranes offer an attractive alternative because they avoid these problems. There are virtually no developed applications for the severe temperature and corrosive conditions encountered in the petrochemical industry. Novel selective energy sources - Most processes proceed by application of substantial amounts of heat, a nonselective energy source. The use of ultrasound techniques enables the reactions to proceed at lower temperatures. Laser systems enable reactions to proceed at lower temperatures because selection of the proper frequency enables activation of the specific chemical bond of interest. Magnetic fields and the use of microwaves have found applicability in biochem· ical systems. Selective reactions with less energy consumption are possible by using alternative energy sources that enhance both the selectivity and conversion at ambient temperatures. Figure 1 provides principal flows and transformations of material in the petrochemical industry - Natural gas -> methanol -> formaldehyde -> adhesives, polyurethanes.

Study Citation:	Pham, H. Q., Marks, M. J. (2004). Epoxy resins.		
HERO ID:	7348912		
Conditions of Use:	Plastic and resin manufacturing		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	In 1994, 433,000 MT of epoxy resin was produced. (5/125)		
Process description:	Melamine– formaldehyde, urea– formaldehyde, and phenol– formaldehyde resins react with hydroxyl groups of high MW epoxy resins to afford cross-linked networks. The condensation reaction occurs primarily between the methylol or alkylated methylol group of the formaldehyde resin and the secondary hydroxyl group on the epoxy resin backbone. The high bake temperatures used in these applications drive off the condensation by-products (alcohol or water). Acids such as phosphoric acid and sulfonic acids are often used as catalysts. These formaldehyde-based resins are widely used to cure high MW solid epoxy resins at elevated temperatures (up to 200C) for metal can, drum, and coil coatings applications. The resultant coatings have excellent chemical resistance, good mechanical properties, and no effects on taste (adding or taking away taste from packaged foods or drinks). The vast majority of the food and beverage cans produced in the world today are coated internally with epoxy– formaldehyde resin coatings. The phenol– formaldehyde resoles are also used with epoxies in coatings for high temperature service pipes and to protect against hot, corrosive liquids. (62/125) Urea– formaldehyde resins can be cured at lower temperatures and faster speed than phenol and melamine–formaldehyde resins and are widely used in the coil coatings industry where cure schedules are extremely short. However, their use has been declining because of concerns over the release of formaldehyde fumes. (99/125)

Conditions of Use:		Processing: Adhesive in resin/wood product manufacturing			
EXTRACTION					
Parameter		Data			
Life cycle description:		""The use of small amounts of amino plastic resins as fortifiers for tannin-based adhesives is not new. The use is new, through, of liquid formaldehyde concentrates as both hardeners and/or fortifiers for such adhesives... Higher concentration of formaldehyde in water can be achieved by partial reaction of the formaldehyde with urea under alkaline reaction conditions, as to form methylol ureas without further condensation to amino-plastic resins. They constitute ideal hardeners for tannin-based adhesives and can very successfully substitute paraformaldehyde, now considerably more expensive. Under certain conditions they can also be used in the function of fortifiers of the tannin/ formaldehyde network.			
Chemical concentration:		""In general liquid formaldehyde concentrates contain approximately 17-23% urea and 50-60% formaldehyde in water solution. The commercial formaldehyde concentrate used throughout this study was BASF Kauresin K244 containing approximately 22- 23% urea and 53-54% formaldehyde ."

EXTRACTION	
Parameter	Data
Process description:	Shell plates composed of either carbon steel or stainless steel are received in flat form. The carbon steel shell plates are edge prepped and cut to size with plasma arc or oxyfuel torches, whereas the stainless steel plates are machine prepped with a plane. The shell plates are rolled into cylinders, tacked with stick electrodes, then welded using a submerged arc process. The end pieces for the tanks are cut into circles (using the aforementioned process) and hot pressed to form the tank heads. Depending upon the size of the tank to be fabricated, various cylinders are assembled together to form the tank shell. The tank end heads are then placed onto the shell and welded with a submerged arc. Submerged arc welding is performed on the interior and exterior seams of the shell assembly. Prior to welding on the shell exterior, the tacks used to temporarily bond the cylinders together are removed by air-arc gouging. After completion of the submerged arc process, the seams are visually patched and ground in preparation for X-raying. Any defects detected in the seams are repaired using a stick electrode. After the basic shell of the tank is completed, various fittings, fixtures, and pads are welded to the assembly. This process may involve tack welding with stick electrodes, flux-cored arc welding shielded with carbon dioxide, and stick/wire electrode welding (for stainless steel). Some of these operations entail considerable welding time and may include both interior (i.e., manways) and exterior welding on the tank car. After these welds are inspected and any repairs made (using stick electrodes), the tank car is stress relieved in an annealing furnace. The gears, yoke, and coupler assembly are then applied prior to having the tank car hydrotested and gauged for capacity. Some of the tank cars are insulated with a fiber material (reported to be fibrous glass) or with a urethane foam. When insulating with the fibrous material, rolls of the material are manually wrapped around the outer wall of the tank. An outer metal shell (jacket) is applied over the insulation. This jacket is welded onto the tank using a wire electrode shielded with a gas mixture of 98% argon, 2% oxygen. Cars which require foam insulation are jacketed and welded using the same process prior to insulation. Either polymethylene polyphenylisocyanate (PAPI), methylene bisphenyl isocyanate (MDI), or occasionally toluenediisocyanate (TDI) are injected inside the void area surrounding the tank car. These urethane foams are also used in forming barrier molds inside the tank and for insulating around the bolsters and sills of the tank. The barrier molds are formed by manually pouring the urethane material into the molds, whereas the bolsters and sills are manually sprayed. The isocyanates are stored in a closed system and pumped to a nozzle where the activator and resin are mixed. The final phase involves the application of valves, platforms, walkways, ladders, rails, and pipes for the brakes and air cylinders. The railroad tank car is then prepared for painting and stenciling. After painting, the tank car is given a final inspection, weighed, and shipped. The fabrication of an aluminum tank car is primarily the same as for a carbon steel or stainless steel car. The aluminum shell plates are edge prepped and cut to size with either plasma arc or oxyfuel torches. These plates are rolled and assembled in a similar fashion except that non-ferrous electrodes are used in the assembly (welding) process. The aluminum cars are also prepared for X-ray; however, a chipping process is used in lieu of air-arc gouging. After X-raying, the fittings and fixtures are applied and the tank is tested and gauged for capacity. From this point, the car proceeds through the same basic fabrication phases as the carbon steel or stainless steel tank cars.
Throughput:	Welding materials used (1976) Flux 446,160 lbs. Submerged Arc Wire 272,546 lbs. Stick Electrodes 258,200 lbs. Flux Core Wire 438,780 lbs Aluminum and 0.045 Gas Metal Arc Wire 103,823 lbs.

HERO ID:	8442687			
Conditions of Use:	abrasive grinding			
EXTRACTION				
Parameter	Data			
Process description:	Process involved is abrasive grinding of steel billets and bloom. The basic function of the facility is the removal of defects from the steel billets and blooms before they are processed in a rolling mill. Billets are pieces of steel ranging in size from 3 7/8 to 7 1/4 inches square with lengths varying from 14 to 41 feet. Blooms have a larger cross-sectional area than billets, with such dimensions as 8 1/2 x 7 1/2 inches and lengths up to 14 feet. Steel billets and blooms are brought in from the primary mill and prepared for inspection by either a descaling process employing sulfuric acid (Pickling) or a Magna-Glo process. Inspection of the steel is performed to determine if any cracks or splits are present which would propagate upon further processing. The actual cleaning is done by first immersing the steel into a sulfuric acid bath at heated temperatures, then into a rinsing tank containing water. Under normal operating conditions the acid is heated to approximately 170 F. In preparation for pickling the blooms are gathered into groups of six and the billets into groups of seven by an overhead crane; these groups are referred to as lifts. During pickling, two lifts of blooms are immersed in each of the two pickling tanks, giving a total of 24 blooms; or three lifts of billets are placed in each tank, giving a total of 21 billets. The “pickle-hooker” and his assistant work in the general area of the tanks where they chain and unchain the lifts in the tanks. These employees are also involved with the addition of ingredients to the tanks. The acid for the tanks is stored outside the building and pumped in when necessary. A chemist analyzes the tanks several times daily for salts, temperature, and percent by weight of sulfuric acid. When the acid concentration is too low or the salt concentration too high, the tank contents are pumped out into underground holding areas, then removed by truck. After the scale has been removed, an inspector examines the lifts to mark any defects that are present. Depending on the number of defects, the type of steel, and operation time available, the steel is sent either to the chippers or to the grinders for further processing. Surface defects are generally removed by hand in the Chipping Area using pneumatic hammers. Those defects which are deeper into the steel are removed through abrasive grinding. Each grinding machine is equipped with a cab to house the operator and with a 110 pound abrasive wheel which rotates at 900 rpm. This equipment is mounted on tracks in order that the grinding wheel can be moved along the steel to be ground. Each operator services 2-3 tables (total of 8 tables) where the billets and blooms are positioned during processing. The finished billets and blooms are then loaded by crane onto railcars to be moved to a rolling mill.

EXTRACTION				
Parameter	Data			
Life cycle description:	Resins, along with drying oils, make up the backbone of surface coatings since they are responsible for the formation of a film with physical integrity and adhesion. Formaldehyde is used in the production of urea-formaldehyde resins and melamine-formaldehyde resins, an important component in the paint and varnish industry. Formaldehyde is also a common raw material for the production of phenolic resins and amino resins.			
Process description:	The manufacturing process for pigmented products appears simple from a schematic viewpoint. Basically, it consists of mixing or dispersing pigment and vehicle to give the final product. The paint vehicle is defined as the liquid portion of the paint and consists of volatile solvent or dispersing medium and non-volatile binder such as oils and resins. The non-volatile portion is also called the vehicle solid or film former. The pigment portion of the paint consists of hiding pigments such as titanium dioxide (TiO2), extenders such as talc or barium sulfate, colorants, and any mineral matter used for flattening or other purposes. Also included in the non-volatile portion of the coatings are various additives present in small quantities for a variety of reasons.

EXTRACTION				
Parameter	Data			
Process description:	There are 16 dialysis locations including 13 consoles for normal care, one unit for isolation, one unit for back-up, and one location for self care. Patients are connected to an artificial kidney (dialyzer) and dialysis console for four hours per visit. Additional time per patient is based on the patient’s diet, condition of the dialyzers being reused, and the general health of the patient. Once the patient is disconnected from the dialyzer, the nurse or technician connects the system for disinfection. All the consoles are disinfected (bleached} daily and sterilized weekly. Once a dialyzer has been used it, as well as the other dialyzers used during that treatment period, are sent to reuse/sterilization for cleaning in a 4% formalin solution. Here one person will spendapproximately 1 1/2 to 2 hours sterilizing all the dialyzers. This procedure takes place in a room approximately 9 X 18 feet and has two doors which are normally closed during sterilization procedures.The last procedure which was thought to contribute to a potentially high formaldehyde exposure occurs on the weekends when the employees are required to pack and sterilize all the consoles. Normally 3 to 5 employees are in the room during this procedure although only 2 to 3 are required to perform the actual process. This process requires the complete draining of each unit followed by filling and packing with a 10% formalin solution. This solution sets in the individual units for the entire weekend and is drained early Monday morning.

EXTRACTION				
Parameter		Data		
Process description:		The Municipal Court Section is responsible for processing all the paperwork generated by the activities in the courtroom, as well as recording the transcripts of court proceedings. A 3M 545 Bond Copier is located in a small room attached to the office area. The actual forms, and major copying comes from the main print room, located in a different section of the building. All forms in this office are on carbonless copy paper. Two large closed-door cabinets located on the south wall of the office holds the 24 different forms used by the staff. The upper shelves of the cabinets are open in back with a narrow space between them and the wall. A four-inch diameter hot water manifold is located in this space which feeds six 2-inch pipes, with manometers, which then run down to the floor behind the closed lower cabinet back. The top of the cabinet, however, runs all the way to the back wall. These pipes are part of a hot water heating system used to heat the building during the winter months. The water temperature in each of these uninsulated pipes reaches approximately 180°fahrenheit when the system is used during the cooler months, and thus creating an extremely warm environment within these cabinets.		
Number of sites:		1		
Chemical concentration:		Laboratory results also found formaldehyde in all of the carbonless copy paper tested. These results showed formaldehyde levels from 2.95 to 9.74 micrograms per sample in the bulk paper tested.

Process description:	The Fort Wayne Foundry Machining Division is not a foundry operation. Approximately 25% of the automotive aluminum castings made in the foundries are machined by this Machining Division. Located in a separate plant which was constructed in 1986, it originally housed only one operation, the 4-3 line. The plant was expanded in 1990 when the 3-1 and quad-4 lines were added, in 1993 when the Cadillac and Saturn lines were added, and in 1994 when the Rochester line was added. At the time of the survey, the Rochester line was not yet operating, but in June 1995, the 4-3, 3-1, and quad-4 lines were scheduled to be shut down and the Rochester line to begin operation. There are two central systems that supply MWF to the machining lines. The 4-3, 3-1, and quad-4 lines are all supplied by system 1, and the other lines are supplied by system 2. Each system consists of a large tank (one that holds 7,000 gallons and one that holds 11,000) under the floor from which MWF is piped to each machine. A series of troughs that run underneath the machines collect the used fluid and carry it back to the central tanks where it is filtered and used again. The MWF is maintained completely by an outside contractor. The contractor tests the MWF in both systems every Monday and then makes the appropriate additions. Based on the pH level and the microbial count, a biocide is added approximately every two to three weeks.

EXTRACTION				
Parameter	Data			
Process description:	Cores are made by a process known as the "Cold Box Process". The process involves mixing a two part organic binder with sand. This mixture is then blown into a core mold where a catalyst is injected through the sand mixture. The core is complete and ready to use at that point. In Department 13, mixing is done by using a Muller which is housed in a back work area. All components of the mixture (silica sand, phenol-formaldehyde resin dissolved in a solvent, and MDI dissolved in a solvent) are measured according to the desired batch size. The binders (added to the sand) are taken in open containers from 55 gallon drums located adjacent to the Muller. Drippings from these drums are collected in small open containers. No local exhaust is provided in this area. In Department 68, the mixing is done in a closed system. Binders and sand (stored outside the work area) are automatically measured and piped to the mixer. From this point on, the operation is essentially the same in both work areas. The mixture (moist sand) is delivered to individual hoppers positioned above the core blow machine. The damp mixture is blown into the core box where it is hardened in less than one minute by blowing the catalyst (DMEA) for a pre set amount of time (depending on the size of the core) and then flushing with air for a preset amount of time. A small line is provided to scavenge waste gas. All core blow machines are provided with a local exhaust system and in all cases DHEA is supplied from a gas cylinder (12% DMEA in carbon dioxide). There are fewer machines in Department 13 and they are positioned further apart. Included also in Department 13 is a hood type exhaust at ground level. In Department 68 the 8 core blow machines are positioned much closer together plus there are two full circle machines. In addition to the employees who operate these machines, two trimmers' work stations are located directly behind one of the full circle machines. These employees trim, piece the cores together, and inspect them.

EXTRACTION	
Parameter	Data
Process description:	The process of making plywood is similar to the veneering phase of the furniture industry. The process consists of gluing thin layers of wood, called plies, together with the wood grain of adjacent layers generally at right angles. Through the years, the types of assembly systems have changed in many plants, hot presses are now used exclusively. In the Pacific Northwest, softwood plywood is manufactured principally from Douglas Fir, although small amounts of cedar, pine, spruce, hemlock, larch, true firs, and redwood are also used. The wet logs are sawed into blocks, debarked, and peeled into veneers. The most common method of producing softwood veneers is rotary peeling done by a knife held parallel to the log axis. A continuous sheet of veneer is peeled and then is dried at about 325°-400°F. Some mills edge-glue dry veneers into 4 by 8 foot sheets. During this study period, an odd number of piles typically were glued together to make a plywood panel. Today, much 4 and 6-ply plywood is also produced. Glue was usually mixed in the mill, and the type of glue used was dependent on the final product desired. Glues were soy or soy-blood blends with some straight blood also used in the production of interior plywood panels in the 1940’s and 1950’s. Pentachlorophenol was often added to the protein glues as a mold preventative. Carbon disulfide increased water resistance of cold-pressed glues, and carbon tetrachloride was premixed with carbon disulfide to reduce fire hazards. Phenol formaldehyde resin was the most commonly used glue in the production of exterior panels in the 1940’s-1950’s. Both urea and resorcinol formaldehyde resins were commonly used as patching glues. Ammonium chloride was added to urea glues as a catalyst; it was not used with resorcinols. There was potential worker exposure to the free formaldehyde released by these resins around the patching operations. A hot or cold-press process was used to bond the panel, depending upon glue type and wood species. During the 1940-1950 period, when soy-blood glues were predominant, the cold pressing process was most common with hot pressing used to some extent. Now, hot pressing is almost universal in Pacific Northwest mills. This is due to virtually a complete switch from soybean and blood-albumin glues to phenol-formaldehyde resins which require hot pressing. Hot presses are usually hydraulically driven and steam-heated to a temperature between 240°-330°F. Panels are pressed for 1-1/2 to 14 minutes for softwoods. Time and temperature varies with the panel thickness and glue type, while the pressure varies with wood species. In softwood plywood mills, panels are usually stacked after removal from the press. This permits retained heat to be used for completing the cure of the adhesive. After pressing, the panels are trimmed to exact dimensions. Depending upon the type of product, the panels may also be sanded, patched, and resanded. Prefinishing and treating are usually not done at the plywood plant but in an operation located elsewhere. The exception is concrete form of lining.

EXTRACTION				
Parameter	Data			
Process description:	The industry has two distinct process stages: wood pulping and paper making. Both may be contained within one mill or may take place in separate locations, depending upon supplies of wood and water. Two chemical processes, sulfate (or Kraft) and sulfite, and one mechanical process, groundwood, were dominant in the pulp industry in the United States during the study period. In 1950, ~25% used sulfate process, 23 % used the sulfite process, and 35 % were groundwood mills. The remaining 17 % used various processes, principally soda and semichemical. By 1974, 11 % sulfite and 20 % groundwood processes, 34 % sulfate, and remaining 35 % was principally composed of the newer defibrated process and semichemical mills, with very few soda and chemimechanical processmills. Of the total US pulp production today(1986), over 60 % is produced in sulfate mills, with less than 10 % accounted for by sulfite mills.

Conditions of Use:	Use of Paints/Coatings			
EXTRACTION				
Parameter	Data			
Process description:	The manufacturing of electric motors at Reliance is a multi-step process. Shafts are cut to length, centered, and machined in one of two lines. Rotors are manufactured by stacking laminations, which are then cast with aluminum on the four cavity die cast machine (rotorcast). The rotors are then broached, and machined on a lathe to define the outside diameter. The rotors are then heated and the shaft is driven in. Heating takes place in a Selas oven or in an induction heater. Together, the shaft and rotor form the rotating assembly. End shields are either machined or purchased. Motor frames begin as rolls of steel, which are cut to size, folded over, and welded. Punch presses are used to produce fan covers and conduit boxes for some motors. Stators are cleated and insulated. Copper wire is wound into coils and inserted into stator cores. Cleated and insulated windings mated with the coil are then varnished. There are two different varnish dipping operations for the stators: hand dipping and machine-applied varnish using the Young Brothers machine. In either case, varnished stators are then baked in an oven. Single-dipped stators have their interior diameter ground to size on a grinding table. Multiple-dipped stators are manually ground. The grinding tools are known as scratch brushes.The various parts are then assembled either in regular assembly, where each assembler puts together each motor, or the parts are loaded on a tray and sent to Progressive Build, a nine position line where each operator performs one or two operations and passes the motor on to the next station. While some pieces are painted as they are completed, and some rotors receive a primer coat, most painting takes place after assembly.

Study Citation:	Rodriguez, M., West, C., Brueck, S. E. (2012). Air contaminant, noise, and dermal hazards during aluminum beverage can manufacturing – Texas.			
HERO ID:	8684526			
Conditions of Use:	Use of printing ink, toner and colorant products containing formaldehyde			
EXTRACTION				
Parameter	Data			
Process description:	The beverage can manufacturing process began by unwinding aluminum sheet metal coils. Aluminum sheets were lubricated with DTI M3 lubricating oil, stamped by the cupping press to produce shallow aluminum cups, then extruded by ironers to form can bodies. The tops of the cans were trimmed to a uniform height. Synthetic MWF (DTI Atoguard I-102B) was used for lubrication and to keep cans and machining tools from overheating during extrusion and trimming. After trimming, cans were cleaned with a heated sulfuric acid solution, etched with hydrofluoric acid, and then rinsed. Henkel Deoxylite 115 was added to the rinse water to help the cans flow smoothly throughout the subsequent printing operation. The rinsed cans were dried, and a thin ultraviolet-cured resin was applied to the can’s base for abrasion resistance. The cans then traveled to one of four printers where an ink label and a varnish coating were applied to the exterior. Three rotary printers each had a maximum production capacity of 1,300 cans per minute, and another printer had a maximum production capacity of 1,800 cans per minute. Isopropyl alcohol was used to clean all the printers. Following printing and coating, the cans passed through one of four gas-powered curing ovens. Curing oven emissions were captured and exhausted through an incinerator. After curing, a protective coating was sprayed inside the cans at the lacquer spray machines. The cans then went through one of three ovens heated to 485°F. Afterwards, a wax film was applied to the top of the cans prior to necking. At necker machines, a flange was formed on the top rim of the cans. The flange was used to form the seal with the top of the cans during filling (a step not performed at this plant). The cans received a final check for damage and were then palletized and shipped to the customer.

HERO ID:	5963848			
Conditions of Use:	Installation/Demolition of Building Materials			
EXTRACTION				
Parameter	Data			
Process description:	World-wide medium density fibreboards (MDF) are manufactured using thermo-mechanical pulps (TMP) as a raw material. Recently, results of research work directed attention to the advantages of using pulps obtained by the chemo-thermomechanical pulping process (CTMP) using a mixture of sodium hydroxide and sodium sulphite for production of MDF. When using phenolformaldehyde resins (PF-resins) and binders based on 4, 4-diphenylmethandiisocyanate (PMDI) as bonding agents CTMP pulps lead to MDF of higher mechanical strength (internal bond and bending strength). However, boards made from CTMP showed generally slightly higher thickness swelling and water absorption in comparison with those made using pulps prepared by the TMP-technique. During the CTMP-process chemical degradation of lignocellulosic materials takes place leading to the formation of low molecular weight compounds, including volatile organic compounds which can be released from the pulps and consequently from the boards prepared therefrom (Konn et al. 2006) In this work, therefore, the influence of the pulping method (TMP and CTMP) on the emission of formaldehyde and volatile organic acids from pulps and from boards prepared therefrom was studied in depth.

HERO ID:	6020303			
Conditions of Use:	commercial use			
EXTRACTION				
Parameter	Data			
Process description:	As a building insulation, urea-formaldehyde foam is generated on-site using portable equipment. A partially polymerized urea-formaldehyde resin is mechanically foamed and then reacts chemically (cures) in place. Three major ingredients are used in the generation of the foam: urea-formaldehyde resin, a surfactant (generally called a foaming agent) which includes an acid catalyst or hardening agent, and air. In general, three types of resin systems have been used to produce the foams on-site. In one, the urea-formaldehyde resin is transported to the job site as an aqueous solution. In another, the resin is brought to the job site as a powder and mixed with water on-site. In the third, the resin is brought to the job site as a concentrated solution where it is diluted with water prior to application. The equipment for generating the foam generally consists of a compressed air pump and a mixing or foaming gun. In the United States the foaming agent catalyst mixture is in general pumped into the gun where compressed air mixes with it and mechanically expands it into foam consisting of small bubbles. The bubbles are then coated in the nozzle of the gun with the urea-formaldehyde resin which has been pumped through a separate line into the gun. The foam, consisting of resin coated bubbles, is forced out of the gun under pressure at which time it contains about 75 percent water by weight. The water is present because the resin and foaming agent were mixed together for chemical reaction as aqueous solutions.

Process description:	For a long time, textiles and clothes have been treated with formaldehyde releasing compounds and resins in order to improve the anti-creasing properties. In 1950s and 1960s, the durable press chemical finishing were based on urea-formaldehyde resin and melamine/formaldehyde resin.		
Chemical concentration:	5000–12000 ppm: 0.5–1.2% in chemical finishing agents for clothes (in the 1950s and 1960s); Studies on the concentration of formaldehyde in clothes detected formaldehyde in 3 of 20 items, with levels of 1391 and 3172 ppm; 75.4-206.1 ppm in clothing per another study; <30-163 ppm in clothes in another study

Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	The assessment or report uses high quality data and/or techniques or sound methods that are from frequently used sources (e.g., European Union or OECD reports, NIOSH HHEs, journal articles, Kirk-Othmer) and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	Medium	The data are from an OECD country other than the U.S., and locality-specific factors (e.g., potential differences in regulatory occupational exposure or emission limits, industry/ process technologies) may impact exposures or releases relative to the U.S.
	Metric 3: Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.
	Metric 4: Temporal Representativeness	High	The report captures operations, equipment, and worker activities expected to be representative of current conditions. The report is generally no more than 10 years old.
	Metric 5: Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics. It is unclear if analysis is representative.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions.
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	High	The report addresses variability in concentration (different studies) and uncertainty in the results.

HERO ID:	1322380		
Conditions of Use:	Office Environment		
EXTRACTION			
Parameter	Data		
Chemical concentration:	The analysis of the bulk sample of Thermo-Lag 300-1 for formaldehyde completed by NIOSH detected no formaldehyde in the sample, the limit of detection was 290 ppm. The bulk sample of Thermo-Lag 300-1 submitted to EMV Associates, Inc. had a formaldehyde content of 344 ppm. This clearly showed that formaldehyde is not a primary constituent of the substance analyzed. The low level present in the material is probably a contaminant of one of the primary ingredients used in this product. Nevertheless, NIOSH suspects that even the very low levels of formaldehyde evident in this product may cause adverse health reactions in certain individuals. (Page 9 of 22)

	Processing (mfg of PF resin)			
EXTRACTION				
Parameter	Data			
Process description:	Borden Chemical is a leading supplier of phenol-formaldehyde (PF) resins used in the forest products industry. These resins are made in batch reactors by reacting phenol and formaldehyde together in the presence of an alkaline catalyst. This is a highly exothermic reaction. The heat of reaction is removed by a large condenser, which condenses the water vapor boiled from the reactor contents and returns it as reflux. The reactor typically holds 10,000 or more gallons and contains a motor driven agitator. The process follows these steps: (1) Water and phenol are charged into the reactor. (2) Vacuum is established in the reactor. (3) Catalyst is charged into the reactor. (4) Formaldehyde is slowly charged to the reactor. As the reaction begins, the heat of reaction brings the reactor contents to a boil at a temperature determined by the absolute pressure in the reactor. (5) Reactor temperature is controlled by adjusting the rate of formaldehyde addition or the reactor -vacuum (which changes the boiling temperature). The heat of reaction is removed by the condenser, with reflux returned to the reactor. (6) After all of the formaldehyde has been added, the batch continues to reflux until the desired polymer characteristics are obtained. This condensation reaction is not as exothermic as the initial methylation reaction. (7) The batch is then cooled, which essentially stops the reaction.

EXTRACTION				
Parameter	Data			
Process description:	The fabric is unrolled on a table in the spreading area, forming many layers of fabric. Pattern pieces are cut from the layers, using scissors or precut dies, and sorted by type. Fabric bundles are then taken to the glue room where the edges are sprayed with an aqueous acrylic emulsion, to prevent ravelling. This operation is performed in a spray booth, in a room adjacent to the sewing area. The fabric bundles are then distributed to the appropriate workstations, where they are sewn and assembled into pants. Conventional sewing machines are used along with a few automated machines for specialized operations such as belt loops. After inspection, the garments are pressed, to form creases, and are then heated in a 325°F oven for a period of approximately 15 to20 minutes, to impart the post-cure. The finished garments are then moved to the packaging area, where they are folded, boxed, and labeled.			
Number of sites:	1			
Chemical concentration:	Table 3 provides formaldehyde concentrations (ug/g of material) for different fabrics that range from 163 to 1430 (also varies whether steam is applied and they are cured).

Process description:	Bromo derivatives cardanolic novolac resins (BCNR) was prepared in the laboratory by bromination of cardanol-formaldehyde novolac resin (CNR) with a viscosity of 170 mPa s (at 75 8C). The synthesis was carried out by the following procedure: a 25% chloroform CNR solution was loaded in a glass flask equipped with a poly(tetrafluoroethylene) stirrer, a reflux condenser, and a thermometer. The whole device was placed in a cryostat. An amount of 30% solution of bromine in chloroform was added dropwise via an addition funnel to the CNR solution over a time period of 5 h. Throughout the process, the temperature of the mixture was maintained in the range of 0.060.5 8C. The mixture was neutralized with 5% sodium bicarbonate solution after completion of the brominating process. Then it was rinsed with demineralized water. Subsequently, the solvent (chloroform) was distilled off in vacuum. Obtained BCNR was a viscous mass of dark brown color with a weak specific smell and viscosity of 64,300 mPa s (at 75 8C).

HERO ID:	5938060
Conditions of Use:	Laboratory Chemical

EXTRACTION	
Parameter	Data
Process description:	Formaldehyde is the preferred chemical for sterilization of the internal hoses of dialysis machines. Two methods were encountered for sterilizing the dialyzers. In one method the 37%-40% formaldehyde is pumped from a container into a central dialysate pump, where it is mixed to produce a 2% formaldehyde solution. The dilute solution is then pumped through the dialysate lines to the dialysis machine. The presence of formaldehyde in the dialysate line at the machine can be verified by one of several different methods which will not be discussed. The second method involves diluting 200 mL of the concentrated formaldehyde to a 2% solution by manually mixing it with tap water in a 1 gallon container. The 2% formaldehyde containers are then placed at each dialysis machine and a "wand" or siphon tube is set inside the container. A "sterilizer" cycle is then activated which pulls the 2% formaldehyde into the dialysis machine. In both procedures the sterilization continues overnight. The next morning the dialysis machines are cleared of formaldehyde by allowing the solution to run into a drain while the machine is rinsed with dialysate. At the end of the drain cycle, the dialysate is checked for the presence of formaldehyde. If formaldehyde is present, the drain cycle is repeated. Another component of the dialysis process is the artificial kidney. Some dialysis clinics reuse the artificial kidneys. During storage, however, they must be kept in a sterile condition, which is maintained by packing the kidney with a dilute formaldehyde solution. To pack an artificial kidney, an employee must run 2% formaldehyde through it and then cap the openings. This is usually done in a standard sink. Ideally, the sink used is equipped with a ventilated hood, but often clean-up sinks are not so equipped. Before reuse, the formaldehyde solution is drained from the kidney and dialysate is used for rinsing.

EXTRACTION				
Parameter	Data			
Process description:	The production processes for making glass wool fiber and filaments are broadly similar. The major differences between glass wool and filaments are that wool is made of blown fibers that have a relatively broad range of diameters (generally <12 um in diameter) and short lengths (millimeters to centimeters), whereas glass filaments are pulled as continuous strands with well-defined, narrow ranges of diameters (6 to 25 um) and lengths of meters. Also, different types of products are made with each. The basic process units for blowing fiber to make wool are diagrammed in Fig. 1. The three important production areas are (1) the furnace and fiberizer area, where the glass is melted and blown into a large chamber over a conveyor (“forming chamber,” fiber for some products is sprayed with a binder as it is formed), after which the airborne fiber is collected by drawing the fiber-laden air through a porous metal conveyor, where it accumulates as a fiber mat; (2) the gas-fired oven, where phenol-formaldehyde binder in the mat is thermoset (“cured”); and (3) the finishing and packaging area, where the fiber product is trimmed, backings and other finishes are applied, and the product is cut to size and packaged in shipping containers that are stored in a warehouse. For some important operations, the mat is not cured in-line, such as for press-formed automotive insulation, or the final form is fabricated in another area, such as for insulation with special coatings or coverings. These processes are performed “off-line,” as shown in Fig. 1, in areas away from the fiber production- line locations. The common processes are diagrammed in Fig. 1. Variations on these basic processes and their plant settings, such as room size, other nearby processes, and local ventilation, can significantly affect the nature and intensity of exposures. The glass filaments are formed by drawing molten glass through a set of holes or nozzles in a metal block, called a bushing. After leaving the holes, the viscous glass filaments are pulled, which reduces the diameter. Filaments are cooled with a fine water spray, coated with starch or other materials, and wound on a cylinder. Continuous filaments are used to produce yarns, roving, textiles, furnace filters, and mat products, such as roofing.			
Chemical concentration:	All but two plants used heat-cured phenolformaldehyde binder to make insulation products. The percentage of binder varied by product type: home insulation fiber mat contains 3% to 5% by weight, board insulation contains 8% to 12%, and tube and automotive insulation contains 10% to 20%.

EXTRACTION

Parameter	Data
Production, import, or use volume:	65,000,000 (kg)
Life cycle description:	Formaldehyde is widely used commercially, most commonly in the manufacture of chipboard and urea-formaldehyde foam insulation. Particle- or chipboard is manufactured from groundwood with urea-formaldehyde as the adhesive, and under certain conditions releases free formaldehyde into the atmosphere. Urea-formaldehyde foam is widely used as cheap and efficient insulation in houses, schools and offices. A resinous mixture of urea, water and formaldehyde is added to a propellant and a surfactant to make a foam, which is mixed on site by the installer, and then injected into the walls of the building.³ In some instances formaldehyde may be released from these walls for up to 3 years. • The amounts released depend on a number of factors such as ventilation, temperature, quality and age of the ingredients, proportions of ingredients used in the mixture, and the skill of the installer. The use of urea-formaldehyde resin in other lacquers and adhesives such as carpet adhesive, parquet floor lacquer, plywood adhesive, paint and wooden furniture adhesives and lacquers constitute additional sources of formaldehyde contamination in the construction industry.³ Formaldehyde is also used to make concrete and plaster impermeable to water and greases. The textile industry uses formaldehyde resins in permanent-press anti-shrink fabrics and for dyeing and flame-proofing. The rubber industry uses hexamethylene tetramine as an accelerator and as a formaldehyde donor in the process of bonding rubber to the steel or textile used in tyres and rubber-metal products. The leather industry uses formaldehyde for tanning and glueing.³ Foundries use it for binding sand and during core-making, and the metal industry uses it as an anticorrosion agent. Formaldehyde is also used commercially as a preservative in cosmetics, in the preparation of drugs, vaccines, fumigants and disinfectants, in the manufacture of other chemicals (e.g. acetylenic products), in the manufacture of fertilizers and other agricultural products, and in the photographic, paper, plastics and protective-coating industries. Welding and the manufacture of electrical machinery are two instances where formaldehyde is released by thermal decomposition of the anti-corrosive resins and plastics used. Formaldehyde in the form of reinforced thermoplastic resins is utilized in the manufacture of a large number of machines, appliances and engines as a replacement for metal in many of the working parts. The medical world makes use of formaldehyde as a tissue preservative in dissecting rooms and histopathology laboratories, as a disinfectant, particularly in hemodialysis units, in the treatment of athlete's foot and, formerly, in the sterilization of hydatid cysts before surgical removal, in vasectomy and in veterinary medicine. Morticians use it as an embalming fluid.⁹ Formaldehyde has been used as a food preservative, a food processing agent and an additive to animal feeds, and as a protein denaturant in the fishing industry. Concentrations have been reported ranging from zero to 30 ppm in a variety of occupational settings.

Parameter	Data			
Process description:	Among the many ways for generating formaldehyde vapor, atomization of formalin is one of the most common. Any sprayer that generates small droplets can be used for this purpose. A problem encountered with sprayers of this type is the build-up of paraformaldehyde about the motor windings. The authors were able to greatly reduce this deposit by locating a filter at the air inlet to the motor. This filter consisted of a 2” layer of coarse oil-treated fiber glass. A device consisting of a siphoning nozzle attached to a formalin reservoir was developed. A source of steam or compressed air was needed for its operation. Steam ejectors have also been used successfully to vaporize formaldehyde from formalin. Another process is vaporization of formaldehyde from paraformaldehyde with heat. This was patented in 1961 by Charles Kaitz and is now used extensively in the poultry industry. His process was to heat a fine white powder containing 91 per cent formaldehyde. Electric fry pans has also been used to vaporize paraformaldehyde. Another process is generation of formaldehyde vapor by reacting formalin with potassium permanganate. Another process is diffusion of formaldehyde vapor from formalin or paraformaldehyde.			
Chemical concentration:	Formalin is 37 per cent formaldehyde in water.

EXTRACTION

Parameter	Data
Production, import, or use volume:	US accounts for 32% of the world's capacity for FA, producing 6 billion lbs per year on average. Consumption of FA in end use products (1980): UF - 29%, 1653 MMlbs (37% solution); PF - 25%, 1425 MMlbs; MF - 5%, 285 MMlbs; Acetal Resins - 5% 285 MMlbs; Butanediol - 7%, 399 MMlbs; Pentaerithital - 6%, 342 MMlbs; Hexamethylene-Tetramine - 4%, 228 MMlbs; Other uses including export - 19%, 1083 MMlbs. Each company, number of plants and capacity of total companies are provided in Exhibit V page 15. Urea, melamine and phenol resin PVs are in Exhibit 29 and 30 pages 79 and 80.
Life cycle description:	Major uses of FA are in the manufacture of urea, phenol, and melamine FA resins which account for nearly 60% of the total, and for a variety of industrial chemicals which account for 25-30%.
Process description:	All FA made in the US are produced from methanol. Two process are used, the silver catalyst oxidation process and the metal oxide or oxidation - hydrogenation process. The former process was the first to be used and accounts for about 80% of US production. The latter process is more efficient in terms of yield and uses on iron oxide - molybdenum oxide catalyst. Silver Catalyst process: the metallic silver catalyst process involves the production of FA from methanol according to 2 simultaneous reactions that occur at atmospheric pressure and temperatures between 600 and 650 C - $\text{CH}_3\text{OH} + 1/2 \text{O}_2 \rightarrow \text{CH}_2\text{O} + \text{H}_2\text{O}$; $\text{CH}_3\text{OH} \rightarrow \text{CH}_2\text{O} + \text{H}_2$; Between 50 and 60% of the FA is formed by the 1st reaction which is exothermic and the remainder by the second reaction, which is endothermic, resulting in a net exothermic process. Overall plant yields of 86 to 90% (based on methanol) are achieved, with CO, CO ₂ , methyl formate and formic acid as byproducts. A flow diagram for a typical plant producing FA by the metallic silver catalyst process is presented in exhibit 7. A brief outline of the processing steps follows. The incoming air (stream 1) is washed with caustic to remove impurities that might poison the catalyst, compressed, and passed through a vaporizer column. It is then heated and saturated with enough methanol vapor (stream 2) to form a mixture that is above the high explosive limit of the methanol (37 vol % methanol). The mixture (stream 3) then enters a battery of catalytic converters where the temp is maintained at about 635 C by the oxidation of either methanol or a portion of the evolved hydrogen. The hot effluent gases (stream 4) are quickly cooled by heat interchange with the feed mixture in the vaporizer and then by introducing the gas into the primary absorber. The liquid in the primary absorber is an aqueous solution of FA and methanol. A portion of this liquid is withdrawn from the bottom of the column and recirculated at the top, and the remainder (stream 5) is pumped to the production fractionation column. The uncondensed vapors from the top of the primary absorption column (stream 6) are fed to a secondary absorber for recovery by contact with demineralized water. A weak FA/ methanol solution (stream 7) is then withdrawn from the bottom of the secondary column for use as make-up solution in the primary absorber. In the product fractionation column, methanol is recovered by vacuum distillation. Methanol vapor from the top of the column is condensed and recycled (stream 9), and uncondensed vapors are vented. The FA solution from the bottom of the column (stream 10) is passed through an ion exchange system to remove trace amounts for formic acid when required, and is then pumped to product storage tanks where water is added to produce a suitable concentration. Metal oxide process: The metal oxide catalyst process, like the silver catalyst process previously described, involved the production of FA from methanol. However in this process, the methanol concentrations are kept below the lower limits of the explosive range, thus all of the FA in this process is produced by the exothermic reaction: $\text{CH}_3\text{OH} + 1/2 \text{O}_2 \rightarrow \text{CH}_2\text{O} + \text{H}_2\text{O}$; This reaction takes place at atmospheric pressure and gives overall plant yields of 88 to 91%. By products include CO, CO ₂ , dimethyl ether, and formic acid. A flow diagram for a typical plant that produces FA by the metal oxide catalyst process is presented in Exhibit 8. A brief outline of the processing steps is presented below. Incoming air (stream 1) is washed with caustic to remove impurities and compressed along with the recycle gas (stream 5). A portion of the compressed air is passed through the vaporizer column where it is saturated with methanol (stream 2). The methanol-saturated air is then mixed with the remaining air and preheated by heat exchange with the product gas leaving the converter. This feed gas mixture (stream 3) then enters the converter, which is maintained at 650 C, by boiling heat transfer fluid (Dowtherm) in the reactor shell. Steam is generated by the condensation of the Dowtherm vapors. The product gas (stream 4) is cooled by heat exchange with the feed gas mixture and then quenches in the absorber column, where the FA and methanol are stripped from the gas stream by absorption in aqueous solution. A portion (60 to 80%) of the unabsorbed gases that exit at the top of the absorber column is recycled (stream 5), and the remaining gas is vented. The product solution drawn from the bottom of the absorber column contains less than 1% of methanol and formic acid. The solution is treated by ion exchange to reduce the acidity and is then stored. Water is added to provide the desired concentration for storage and shipping. It takes 0.42-0.43 lbs of methanol to produce 1 lb of FA (37% solution) by the silver catalyst process and 0.43-0.46 lbs methanol by the metal oxide process.
Number of sites:	15 US companies produce FA at 56 plant sites. 110 firms in the US are producers of resins, plastics or adhesives with FA in formulation.

Parameter	Data		

Process description:

The Electric Machinery - McGraw Edison factory has been involved in manufacturing various sizes (5 1/2 - 12 1/2 diameter) of electric generators/motors since 1926. The epoxy resin materials and processes which are used for electrical component encapsulation and insulation have been in operation since 1971. There are several different types of heat setting epoxy materials used. 1. Coil Winding and Hand Taping The coil winding and hand taping areas, located on the second floor of the facility. There are about 6 employees in the coil winding department and 30 employees in the hand taping area who work on a one shift. The hand taping area is temperature and humidity controlled and "person-cooling" fans are occasionally used to enhance or provide dilution ventilation. The work processes in the coil winding area begins with the loop winding operation. In this procedure, copper wire (purchased outside: coated with fiberglass and varnish) is staped (mylar)® into a rectangular-shaped coil approximately 5' in length. The coils are then placed on one of three different sized compressed-air-powered coil forming machines. Coils are spread to appropriate lengths and widths and employees make adjustments using hand-held, steel-headed mallets and pinching/crimping tools. The hammering and crimping actions performed by the coil forming employees are a potential contributing factor to the biomechanical stresses experienced by the workers. Soldering the coil's copper leads is the last procedure done in the coil winding department. From the coil winding floor the coils are sent to the hand taping area. The mylar tape which had been previously applied, is removed from the coil. Mica-paper is manually applied to the low voltage coils in 36 1/2 wide sheets and also to the high voltage coils in 3/4", 1", or 1 1/4" tape form. The number of layers of mica-paper or mica-tape applied to the coil varies with coil voltage specifications. Epoxy impregnated felts are inserted between the leads of the coil and mylar tape is wrapped around the leads. Dacron-fiberglass "outer-binder" tape is applied to all coils for protective purposes and a special dacron tape is occasionally applied to some high voltage coils for quality control testing. In order to alleviate some of the ergonomic stresses associated with wrapping several layers of tape around the coils, several employees use a hand-held, non-powered winding spindle to apply the tapes. However, this tool is not used by all the hand taping employees. Several of the employees use wrist length, perforated leather or vinyl protective gloves (with finger slots removed) to aid in preventing blisters and/or callouses caused by the repetitive wrapping motions incurred with application of the tapes. Water soluble protective skin creams are used by some employees to avert dermatitis. The average high voltage coil process time through the hand taping department is 2 hours whereas the low voltage coil takes 25 minutes. Upon completion, the finished coils are sent to the armature winding floor or VPI room. 2. Armature Winding and VPI The VPI room and armature winding area each cover about 4000 square feet. There are about 20 employees in the armature winding area and one employee in the VPI room per shift. During the NIOSH survey, the armature winding and VPI system employees worked on a two shift, 5-day, 8-hour-per-day schedule. Occasionally, however, the armature winding department operates on a 6-day work schedule. The work processes in the armature winding area begins when the copper conductor coils, which were previously wrapped with the epoxy embedded mica tapes, are brought into the winding area and warmed to room temperature. The coils are manually inserted into the core of the generator and lashed in place with wire. The leads are soldered together using a rosin core solder and the coil is insulated with the epoxy resin embedded felts, mica tapes, and other tape-binding materials. Other work processes on the winding floor using epoxy materials include the use of an epoxy glue to adhere temperature detectors onto the generator and an epoxy resin and an epoxy resin kit and mica tape for use in making minor repairs on new and old electric generators. From the winding floor, the coil/core assemblies are sent to the VPI room where the VPI operators apply the MRV-1000, a silicon release agent, manually by brush. After warming in the preheat oven (150°F for two hours) the coil/core assemblies are placed into the VPI tank which is 10' in diameter and has a capacity of about 5000 gallons. The sequence of processes in the VPI tank includes a dry vacuum cycle (1-1 1/2 hours), wet vacuum cycle (epoxy resin - 2 1/2 hours), and pressure cycle (90-110 lbs for 6-10 hours). When coil/core assembly is removed from the VPI tank, it is placed in the final cure gas-fired baking oven for about 2 hours at 150°F and 10 hours at 300°F. Some machines are recycled through the VPI system. If the generator passes electrical tests, then excess resin is cleaned off the generator using compressed air-powered sanders and buffers and non-powered file-scrappers. Following the cleaning, the motor is sent to the assembly floor area. Due to their size, the largest generators/motors, B-stage coils, are slightly modified in regards to their processes of manufacture. The conductor coils, brought from the coil winding department, initially go through the VPI system separately, on racks, and are partially cured. On the winding floor the half cured coils are inserted into the generator cores, leads are soldered, and the insulating epoxy mica felts and tapes are put into place. Occasionally, liquid epoxy resin is painted on the completed generator manually by brush. The motor is finally cured in large gas-fired ovens as a single unit. Another VPI system, located in the VPI room, for the smaller generators, operates on a similar basic process. Unlike the large B-stage generators, the smaller generators are processed through a small VPI tank (5 1/2 diameter with 500 gallon capacity) wherein liquid epoxy resin impregnation occurs. Welding (conventional shielded metal arc or consumable flux coated electrode) is performed on the generator frames in the winding area.

Conditions of Use:	Compressed Wood Product Manufacturing			
EXTRACTION				
Parameter	Data			
Life cycle description:	Fiberboard is a dense pressed wood product produced in boards of various thicknesses (3/16 to 1½ inch) for furniture, and in other shapes for interior applications such as baseboard moldings,cabinets, and picture frames.			
Process description:	The highly automated manufacturing process consists of: preparing wood fibers, treating fibers with urea-formaldehyde resin and drying them, forming mats of resin-treated wood fibers, pressing the mats into fiberboard, and finishing the boards with sawing and sanding. The raw materials are moved by the front loader operator from large piles outside into a wood storage shed. The wood chips are softened with steam pressure in the digester and ground into fibrous material at the refiner. A refiner operator controls the process from an isolation booth. In an enclosed process, liquid urea-formaldehyde resin is injected into the fibrous material, and the fibers are then dried to about 10% water content. During the drying process, the resin is drawn into the porous fibers. After drying, resin-treated fibers are conveyed to the former, which layers the fibers into a continuous 4-ft wide mat. The mat consists of two “face” layers on the top and bottom and two inner “core” layers; the face and core layers have resins of different composition. The continuous mat is fed onto a form line conveyer, where the mat is leveled to a specified thickness and cut into separate 8-ft mats by an automatic “flying” circular saw (form line saw). The mats are conveyed into a pre-compressor, where excess air is pressed out, and then are loaded into a 20-opening steam-heated hydraulic press. Mats are pressed at 1500-3000 pounds per square inch at 300-350 °F for specified times to cure the resin and bind the wood fibers together into a dense board. Steam and vapors are emitted when the hot press opens are exhausted through roof openings over the press. The boards are unloaded from the press onto an enclosed cooling wheel where they are cooled with outside air that is moved over the boards and then exhausted to the outside. The boards are then stacked and moved by forklift to a warehouse area, where they are allowed to continue cooling for a minimum of 24 hours. Cooled fiberboards are cut to exact dimensions (usually 4 ft x 8 ft) by an automatic in-line saw,then moved to the sander, which removes the top and bottom surfaces to produce the finished fiberboard product.			
Number of sites:	1 site studied			
Chemical concentration:	formaldehyde concentration in settled dust was measured[Table 3]: Formaldehyde in Bulk Samples of Settled Dust (Second Site Visit) Table 3Wood Storage shed- dust on catwalk railing- 0.04(BDL, MDC/2 is reported, NIOSH 5700), 0.009(Value between MDC and MQC, Elia et al.) Wood chip pile outside- 0.03(BDL, MDC/2 is reported, NIOSH 5700), 0.004(BDL, MDC/2 is reported, Elia et al.)Blender room- next to area air sample- 2.31(NIOSH 5700), 0.431(Elia et al.)Core Line- untreated dried wood fibers- 0.05(BDL, MDC/2 is reported, NIOSH 5700), 0.006(BDL, MDC/2 is reported, Elia et al.)Form Line- next to area air sample- 2.16(NIOSH 5700), 0.321(Elia et al.)Sander operator station- dust on catwalk- 0.12(Value between MDC and MQC,NIOSH 5700), 0.120(Elia et al.)Form line- fibers face mat on line- 0.15(Value between MDC and MQC, NIOSH 5700), 0.275(Elia et al.)Board cooler- dust on floor next to machine- 1.13(NIOSH 5700), 0.145(Elia et al.)Sander dust- from silo outside building- 0.91(NIOSH 5700), 0.167(Elia et al.)			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1: Methodology	High	The assessment or report uses high quality data and/or sound methods that are from frequently used sources (NIOSH HHEs).	
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States	
	Metric 3: Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.	
	Metric 4: Temporal Representativeness	Low	Study implemented from 1991 and 1993 - 28 years old	
	Metric 5: Sample Size	Medium	Statistical distribution of samples is fully characterized. Sample size appears to be low (~2 samples per location)

Domain		Metric	EVALUATION	
			Rating	Comments
Metric 6:		Metadata Completeness	High	Clearly noted that information provided came from site visit and provided methodology that measured formaldehyde in bulk samples.
Domain 4: Variability and Uncertainty				
Metric 7:		Metadata Completeness	High	sufficient data are provided to assess variability between locations and uncertainty is addressed by discussion on appropriate sampling methodology and two different analytical methodology.
Overall Quality Determination			High	

Study Citation:	Sussell, A. L. (1990). Heta 89-335-2041 May 1990 Sheffield Lake Service Department Sheffield Lake, Ohio.			
HERO ID:	8156936			
Conditions of Use:	Fuels and related products			
EXTRACTION				
Parameter	Data			
Process description:	On a daily basis, diesel trucks are driven into the maintenance shop, consisting of a single service bay located in the southwest corner of the building. It is periodically necessary to run the truck engines in the maintenance shop during servicing. During the winter months, diesel-powered trucks are parked in the five garage bays overnight to keep the engines somewhat warmer than outside conditions. From 7:00 to 7:30 am, trucks to be used that day are started and run for 1 to 2 minutes, then pulled outside. The running time in the building reportedly is necessary to allow for the air brakes to become pressurized, and for the older-model truck engines to briefly warm up. (2/13)

Study Citation:	Taylor, A. W. (2004). Fertilizers. :111-128.		
HERO ID:	11203989		
Conditions of Use:	Commercial Uses - Chemical substances in agriculture use products - Lawn and garden products		
EXTRACTION			
Parameter	Data		
Production, import, or use volume:	Table 1 (pg 3) presents annual world consumption rates of N, P2O5, and K2O for various years 1930-1999; 138.3 Mts/yr total nutrients in 1999		
Process description:	Urea-formaldehyde (38% N) and isobutylidene diurea (IBDU, 31% N) are specialized materials developed as “slow-release” nitrogen fertilizers. Both are polymeric compounds made by reacting urea respectively with formaldehyde and isobutyraldehyde. Both are insoluble in water, and, in the soil, both hydrolyze to release urea at a rate that depends upon the granule size, which can be varied to control the rate of nitrogen release. (pg 7)Fertilizers are applied as fluids, dry bulk, or bagged granulated materials. Considerable amounts of nitrogen are used as “direct applications” of this single nutrient, either by surface applications of urea, ammonium nitrate, or sulfate or by the injection of gaseous ammonia or “aqua ammonia” solution into the soil. The use of these latter high nitrogen content fluid materials has steadily increased due to their ease of handling and application to row crops; they are also well suited for use by contract suppliers and applicators who formulate and apply fertilizers to the field as requested by the farmer.Mixed formulations containing two or three nutrients are used as dry materials made by the blending of granular materials in bulk or in fluid forms made by blending fertilizer solutions3. About one-half of the fertilizers used in the United States are applied as mixed formulations, and about three-fourths of these are used as bulk materials or in solution. The fraction used as dry bagged materials—as opposed to those supplied and used in bulk—has steadily declined over the last 30 years, reflecting the reduced transport costs of bulk materials and the growth of the contract applicators as part of the farm support industry (pg 13)There are several principal techniques for fertilizer application in the field. These include: 1) surface broadcasting without incorporation into the soil, 2) surface application with immediate incorporation and placement in the soil by an attachment to the plow or cultivator, and 3) the injection of liquids and gaseous formulations by pumping through cultivator knives. Applications are also made in irrigation water for crops grown with such water supplies. (pg 14)		
Throughput:	Amount of fertilizer nitrogen: maximal values of about 250 kg/hectare (pg. 2)		
Chemical concentration:	No concentration data for FA/Urea-FA, other than 38% N in urea-FA		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	Report uses high quality data from frequently-used sources.
Domain 2: Representativeness	Metric 2: Geographic Scope	High	Data are from the U.S.
	Metric 3: Applicability	Medium	Data are for fertilizers, an in-scope occupational scenario; however, majority of data are not formaldehyde-specific.
	Metric 4: Temporal Representativeness	Medium	Report is based on data greater than 10 years old but less than 20 years old and industry conditions that are expected to be outdated.
	Metric 5: Sample Size	N/A	Not applicable no quantitative data on formaldehyde
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	Medium	Assessment or report clearly documents results, methods, and assumptions. Data sources are generally described but not fully transparent.
Domain 4: Variability and Uncertainty	Metric 7: Metadata Completeness	Medium	Variability addressed by providing data for different nutrient types but uncertainty is not addressed.

HERO ID:	1970347				
Conditions of Use:	Use of Metalworking fluid				
EXTRACTION					
Parameter	Data				
Process description:		The article deals with aerosols in machining plants. Aerosols of metalworking fluids (MWF) are generated in the process of cooling, flushing, and lubricating machine tools and metal parts during machining operations such as drilling, grinding, honing, hobbing, and milling. While mineral oils are most commonly used for honing, these other machining processes use water-based MWF, typically containing 2 to 20% emulsified oil. These MWF systems become complex mixtures of water, emulsified oils, antifoam agents, rust inhibitors, biocides, microorganisms, and microbial products.

Study Citation:	TVA, (1991). Formaldehyde in urea product and urea production – status report with cover letter dated 02/01/91 and attachments.			
HERO ID:	5899360			
Conditions of Use:	Processing into a formulation- Fertilizer (Urea)			
EXTRACTION				
Parameter	Data			
Process description:	Formaldehyde has been widely used in the production of urea since the mid-1970’s as a conditioning agent to harden the product; reduce dust generation during handling; and provide anti-caking properties in storage. Formaldehyde reacts with molten urea in the process to form principally methylenediurea			
Throughput:	Production rates on 5 days in 1980 were between 10,200 lbs/hr and 32,000 lbs/hr and formaldehyde concentration in these products ranged between 0.36 and 0.57 wt percent. Table II contains production rate of formaldehyde in ml/min ranges from 2340-2406.			
Chemical concentration:	Up to 0.6% formaldehyde is added to the urea melt prior to granulation or prilling commercial urea fertilizer. Total formaldehyde in urea samples ranged from 0.3 to 0.55%. Free formaldehyde was determined to be 0.01% or less in all urea samples.

EXTRACTION	
Parameter	Data
Process description:	Formaldehyde is produced in the United States by two methods: the metallic silver catalyst process and the metal oxide process. The silver catalyst process is the predominant process, accounting for 75% of formaldehyde manufactured, while the metal oxide process accounts for the remaining 25 %. Both production methods use methanol as the starting material. Silver Catalyst Process – The major products of the silver catalyst process are formaldehyde, hydrogen, and water. Actual flow diagrams for production facilities will vary. Compressed air, which has been scrubbed to remove traces of sulfur dioxide, hydrogen sulfide, and other impurities, is passed through a vaporizer column, where it is heated and saturated with methanol vapor. The heated stream must maintain a methanol concentration greater than 37 volume percent in order to be above the upper explosive limit of methanol. The mixture then enters a battery of converters that are maintained at a temperature of approximately 635°C. The hot effluent gases are cooled rapidly to prevent decomposition of the product formaldehyde. Cooling is accomplished by indirect heat interchange with the feed mixture in the vaporizer and by then introducing the gas into the primary absorber. The primary absorber liquid is an aqueous solution of formaldehyde and methanol. A portion of this liquid is withdrawn from the bottom of the absorber column and recirculated to the top. The remainder is pumped to the product fractionation column. The uncondensed vapors and noncondensable gases are withdrawn from the top of the primary absorber column and fed to a secondary absorber. The major portion of the uncondensed vapors is recovered in the secondary absorber column through contact with demineralized water, and the off-gas, consisting mostly of nitrogen with some entrained volatile organic compounds (VOC's), is vented. The weak formaldehyde/methanol solution withdrawn from the bottom of the secondary absorber column is pumped to the primary absorber column and used as makeup solution. The methanol-containing formaldehyde solution is pumped to a fractionation column, where methanol is recovered. This vacuum distillation step yields an overhead product of approximately 99% methanol for recycle to the reactor and a bottom product of formaldehyde solution containing less than 1% methanol. The methanol vapor from the top of the column is condensed and recycled to the vaporizer. Uncondensed vapors are vented or fed to the absorber. The formaldehyde solution from the bottom of the fractionation column is pumped to product storage tanks. When required by customer specifications, the solution is treated in an ion exchange system for removal of trace amounts of formic acid before being stored. As a final step, water is added to provide a suitable concentration for storage and shipping. Reported yields for the metallic silver catalyst process range from 83 to 92%. All product storage tanks are heated to prevent polymer formation and precipitation in storage. A series of tanks are used to blend and adjust the solution to the desired formaldehyde and methanol concentrations before it is shipped to the customer. Metal Oxide Catalyst Process– In the metal oxide catalyst process, the major products are formaldehyde and water. The catalyst system most often used is ferric molybdate. The process begins as incoming air, which has been scrubbed to remove dust and trace impurities, is mixed with oxygen-lean recycle gas from the process to lower the oxygen content of the air feed stream below 10.9%. This low oxygen content keeps the methanol concentration below the lower explosive limit when a portion of the air feed stream is saturated with methanol in the vaporizer column. The methanol-saturated air is then mixed with the remaining air and preheated by heat exchange with the product gas leaving the converter. The feed gas mixture then enters the converter, which is maintained at 345°C by the exothermic oxidation reaction. The product gas is cooled by heat exchange with the feed gas mixture and then quenched in the absorber column. The formaldehyde and methanol are removed from the gas stream by absorption in the aqueous solution. The unabsorbed gases and vapors exit at the top of the absorber column. A portion of this gas is recycled, and the remaining gas is vented. The product solution drawn from the bottom of the absorber column contains approximately 0.8% methanol and 0.005% formic acid. The solution generally is treated in an ion exchange system to reduce the acidity and is then stored. As a final step, water is added to provide a suitable concentration for storage and shipping. Process yields of 91 to 93% are reported for the metal oxide catalyst process.

Parameter	Data			
Process description:	Amino resins generally are produced in a batch reactor but some are produced in closed continuous systems. The first reaction of the process, the addition of formaldehyde to the amino compound to form methylol compounds, is carried out under alkaline conditions. Caustic, formaldehyde, and the amino compounds are charged to the heated reaction vessel. Next, the reactor conditions are altered to favor the second reaction, the condensation of the methylol compounds to form a polymer chain. The condensation reaction is carried out under acidic conditions and is stopped at the desired degree of polymerization by lowering the temperature and raising the pH. At high degrees of polymerization, a solid polymer is produced. At low degrees of polymerization, a stable syrup is produced that can be used as an adhesive or laminating resin. The syrup can be combined with a filler to make a molding compound or used with other polymers in coatings formulations. The syrup can also be spray dried to form a powder for convenient storage and handling. However, some producers of U-F and M-F resins report that there are no spray drying operations at their production facilities.

EXTRACTION	
Parameter	Data
Process description:	Phenol-formaldehyde resins are formed by polymerization of phenol and formaldehyde. The two major resin types are resols and novolaks. Resols are formed in an alkaline medium with an excess of formaldehyde and are marketed as thermosetting resins, bonding resins, varnishes, and laminates. Novolaks are formed in an acid medium deficient in formaldehyde. These are thermoplastic resins that require mixing with formaldehyde or a formaldehyde donor such as hexamethylenetetramine to produce a thermosetting product. Resol Production Process– Resols are commonly produced in a batch process. Major products of the resol production process are phenol-formaldehyde resin and water. Phenol, formaldehyde, and sodium hydroxide are charged to an agitating reactor. Steam is then fed to the kettle jacket and to internal coils to initiate the reaction. As the exothermic reaction begins, cooling water is supplied to the kettle to maintain temperature control. Additional cooling is accomplished by using a reflux condenser. The degree of polymerization is monitored by withdrawing samples and testing them. The degree of polymerization determines the physical properties of the product. The reaction can be halted at a point where the polymer is still water soluble enough that it can be incorporated into bonding resins. Alternatively, the reaction can be allowed to progress to the point at which the polymer precipitates. In this case, the water is removed and an organic solvent can be added to form a varnish. If the polymerization reaction is allowed to continue until the resin reaches a brittle stage, a thermosetting molding powder can be produced. The polymerization reaction is stopped by rapid cooling and neutralization with sulfuric acid. The mixture is then distilled in the reactor kettle to purify the resin. If the resin application requires a low concentration of water, the resin is dehydrated, often under vacuum. The production of dry product requires discharge of the resin from the reactor through a special quick-discharge valve to prevent it from becoming an insoluble, infusible solid. Cooling must be accomplished by spreading the material in thin layers because of its low thermal conductivity. Cooling devices include water-cooled or air-cooled floors, trays in racks, and moving belts. After cooling, the solid is ground, screened, and packaged. Some of the solid resols require several water washing steps. This procedure necessitates drying the resin before it is packaged. The solid resin may be blended with fillers and additives before it is readied for marketing. Novolak Production Process – The production of novolak resins is also commonly performed by a batch process. As in the production of resols, phenol and formaldehyde are charged to a jacketed batch reactor. However, sulfuric or hydrochloric acid is added instead of a base. The temperature is raised to initiate the reaction. If strongly acidic conditions are used, a vacuum reflux system must be used for cooling, but in many cases atmospheric reflux is sufficient. Additional cooling is provided by circulating cooling water in the jacket and in the internal coils of the reactor. When the reaction is completed, the resin is purified by distillation in the reactor kettle and subsequent dehydration. In some cases, the polymer is neutralized before it undergoes further processing. In solid resin production, the reactor charge is dumped onto cooling surfaces in thin layers. Water-cooled or air-cooled floors, trays in racks, and moving belts are used for rapid cooling. The solid resin is then ground, and screened. Fillers, coloring agents, and hexamethylenetetramine may be blended with the resin, which can then be fused on hot rollers, ground and packaged as a finished thermosetting resin product. During the production of solutions used in varnishes and laminating agents, solvent is also added in the reactor. The solutions are packaged in drums or tanks.

Parameter	Data			
Process description:	POLYACETAL RESIN PRODUCTIONAcetal resins are produced by the polymerization of anhydrous formaldehyde or its trimer, trioxane. Formaldehyde and trioxane homopolymers and copolymers of these compounds and other monomers are produced. The homopolymer is a chain of repeating oxymethylene structures (-OCH2-), while the copolymer has the oxymethylene structure occasionally interrupted by a comonomer unit such as ethylene. Where formaldehyde is to be polymerized, the first step in the process is the production of anhydrous formaldehyde vapor from formaldehyde solution. Water is first evaporated from aqueous formaldehyde solution to form semiformals, paraformaldehyde, and polyoxymethylene which are purified and thermally decomposed to produce anhydrous formaldehyde. Impurities such as methanol, formic acid, and water are removed by washing with nonvolatile polyols or by freeze-trapping slightly above the boiling point of formaldehyde.Anhydrous formaldehyde monomer is then fed to an agitated batch reactor with an inert diluent, initiators, and dispersants, where it is polymerized at a low temperature. The polymer molecular weight is controlled by the addition of chain-termination and transfer agents. The reaction is terminated by stopping the flow of monomer. The solid polymer is separated from the diluent by filtration and centrifugation. Chain ends are stabilized by treatment with acetic anhydride and refluxing to form acetyl groups. The final product is then washed and dried. In trioxane polymerization, trioxane is prepared from aqueous formaldehyde by acidification and distillation. The trimer is then separated from the aqueous distillate by extraction or crystallization before it is further purified by fractional distillation. Trioxane may then be polymerized by bulk, suspension, or solution methods in the production of the copolymer. Stabilization is accomplished by copolymerization with cyclic ethers.The final polymer is extruded. Additives may be added during extrusion. Extruded molten polymer strands are quenched in a water bath and then pelletized and stored.

Conditions of Use:	combustion - oil refinery

EXTRACTION	
Parameter	Data
Process description:	Combustion Oil RefiningFormaldehyde is produced as a combustion product in a number of refinery operations. The major sources of formaldehyde emissions from oil refining are catalytic cracking, coking operations, and fuel combustion.Process heaters are used in almost every refinery unit operation to heat feed materials or to supply heat in distillation operations. They are designed to provide temperatures up to 510°C and can be fired by refinery fuel gas (usually CO-rich), natural gas, fuel oil, or oil/gas mixtures.Heat for refinery operations is also provided by steam, which is produced in boilers in the refinery utilities plant. These boilers generally are fired by fuel oil or oil/gas mixtures.At older refineries, high-pressure compressors are often run by natural gas-fired internal combustion engines. High-pressure compressors are used in hydrodesulfurization, reformation, and other refinery unit operations. Because of their greater reliability, electric motors and steam engines are used at most newer refineries in place of gas-fired engines. The total amount of fuel burned at a refinery dependson the size and complexity of the refinery. The breakdown of fuel use between fuel oil and gas depends on the availability of fuels, the particular requirements of various burners or engines, and applicable environmental (e.g., fuel sulfur) regulations. It is estimated that for a large complex refinery, the total fuel requirement is 230 Gigajoules (GJ) heat input per barrel (bbl) of crude feed, of which on the average about 70 percent is provided by fuel oil combustion and 30 percent by fuel gas combustion.Catalytic Cracking– In catalytic cracking, catalysts are used to break down heavy oils to lighter products. Feedstocks to catalytic cracking typically have a boiling range of 340 to 540°C. Catalytic cracking Processes currently in use can be classified as either fluidized catalytic cracking (FCC) units or moving-bed catalytic cracking units. In both processes, fresh and recycled oil are fed to a cracking reactor with hot regenerated catalyst. The reactor temperature for both processes is 470 to 525°C.In the FCC process, the oil vaporizes, and the catalyst, made up of very fine particles, becomes entrained in the vapor. The cracking reaction takes place as the fluidized-catalyst/oil-vapor stream flows up a riser in the center of the reactor. The catalyst and oil vapor are separated by cyclones at the top of the reactor. Spent catalyst from the cyclones falls to the reactor bottom where it is steam-stripped to remove adsorbed hydrocarbons before flowing out of the reactor.In the moving-bed process, catalyst beads (about 0.5 cm in diameter) are fed to the top of the reactor along with a mixed-phase oil feed. Cracking occurs as the catalyst and oil move concurrently downward through the reactor. Hydrocarbons are separated from the catalyst in a zone near the reactor bottom. Spent catalyst is then steam-stripped of adsorbed hydrocarbons and flows out of the reactor.Oil removed from the FCC catalytic cracking process is fed to a fractionation column, where it is split into gas and liquid product streams and a recycle stream. Spent catalyst in both processes is transferred to a regenerator, where coke deposits are removed from the catalyst surface by partial combustion with air at 590 to 675°C. Regenerated catalyst is separated from combustion products by cyclones and returned to the cracking reactor. Because the combustion process in the regenerator is incomplete, flue gas from the regenerator generally has a high CO concentration. Coking–Coking involves the thermal cracking of heavy residual oil to form lighter products and petroleum coke. Two types of coking processes are currently in use: fluid coking and delayed coking. In delayed coking, feed oil is heated to 480 to 580°C in a process heater and then fed to one of two coke drums. Cracking occurs as the oil flows through the heater, and light products are removed as an overhead vapor stream from the drum. Heavy liquids remain in the drum to form coke. The delayed coking process is a batch process. When the drum in use is filled to capacity with coke, the stream from the process heater is fed to the second drum. Meanwhile, coke is removed from the first drum with high-pressure water jets.In the fluid coking process, feed oil is contacted with hot pellets or seed coke particles in a fluidized bed reactor. The feed oil cracks, forming coke, which remains on the particles, and light products, which flow out of the reactor in an overhead stream. Fluid bed particles are removed continuously from the reactor and circulated through a burner. In the burner, the coke is partially combusted with air. A portion of the coke leaving the burner is removed as product, and the remainder is returned to the reactor. The continuous circulation of reactor bed material through the burner provides heat for the cracking reaction, transferred as sensible heat in the bed material. The reactor temperature is maintained at 525to 580°C. Flue gas from the fluid coker burner off-gas contains incomplete combustion products including a large amount of CO. Carbon monoxide emissions generally are controlled by passing the flue gas through a CO waste heat boiler.

Parameter	Data
Process description:	SOLID UREA AND UREAFORM PROCESSINGProcess Formaldehyde is used in the production of conditioning agents for solid urea and in the production of ureaform fertilizers.Solid urea is produced by first reacting ammonia and CO2 to form an aqueous urea solution. This solution is sold as an ingredient in nitrogen-solution fertilizers or further concentrated to produce solid urea. Urea solids are produced from the concentrated solution by two methods: prilling and granulation. Prilling is a process by which solid, nearly spherical particles are produced from molten urea. Molten urea is sprayed from the top of a prill tower, and as the droplets fall through a countercurrent air flow, they cool and solidify into nearly spherical particles. There are two types of prill towers: fluidized bed and nonfluidized bed. The major difference between these towers is that a separate solids cooling operation may be required to produce agricultural-grade prills in a nonfluidized bed prill tower.There are two granulation methods: drum granulation and pan granulation. In drum granulation, solids are built up in layers on seed granules in a rotating drum granulator/cooler approximately 14 feet in diameter. Pan granulators also form the product in a layering process, but different equipment is used. Pan granulators are not common in this country.Just prior to solids formation, formaldehyde-based additives (FBA's) are injected into the liquid or molten urea to harden the product, reduce dust generation during handling, and provide anticaking properties for storage. The two most commonly used FBA's in the fertilizer industry are formalin and urea-formaldehyde (U-F) concentrates. Formalin is an aqueous formaldehyde solution stabilized with methanol, whereas U-F-concentrates are a solution of 25 weight percent urea, 60 weight percent formaldehyde, and 15 weight percent water. Upon injecting FBA into the liquid or molten urea, formaldehyde reacts with urea to form methylenediurea (MDU), which is the true conditioning agent. FBA is usually added to urea at a level of 0.3 to 0.5 weight percent formaldehyde.Ureaform is a slow-release fertilizer produced from a mixture of urea, U-F-concentrate, sodium hydroxide, and water. The reaction to produce ureaform is initiated by adding acid, forming a wide distribution of methylene-urea polymers, similar to the MDU in solid urea. The initial concentration of formaldehyde in the ureaform process is much higher than in solid urea production.Emission sources

Process description:	PENTAERYTHRITOL PRODUCTION Formaldehyde is produced onsite at some plants for direct use as a feedstock in this process. Pentaerythritol is made by the condensation reaction of formaldehyde and acetaldehyde in the presence of an alkali solution. Most plants use a batch process.A sodium hydroxide solution or a calcium hydroxide slurry is added to a formaldehyde solution in a reactor in which the temperature is controlled at 15° to 20°C. Liquid acetaldehyde is then added to the mixture and an exothermic reaction takes place. External cooling is used to control the temperature at about 25°C for several hours, and it is then raised to about 60°C.When the aldehyde content of the mixture is less than 0.1 percent, the reaction mixture is fed to the neutralizer tank where formic acid, sulfuric acid, or oxalic acid is added to neutralize the excess alkali. The acid also reacts with the metallic ion of the alkali solution to form a salt, which can be removed by filtration. Next, the solution is fed to an evaporator, where water is removed to achieve a specific gravity of about 1.27. Lowering the temperature results in the crystallization of pentaerythritol, which is removed from the slurry by filtration. The mother liquor is fed to a recovery system. The filter cake can be dried to yield a technical grade of the product or it may be purified further by conventional methods. Byproducts of the reaction include polypentaerythritols (mainly dipentaerythritol and tripentaerythritol) and linear and cyclic formals of the various pentaerythritols.

Process description:	4,4-METHYLENEDIANILINE PRODUCTION4,4 1-Methylenedianiline (MDA) is formed by condensation of aniline and formaldehyde. MDA is usually converted into methylenediphenyl isocyanate (MDI) by phosgenation of the MDA salt. The production of MDA is a two-stage process. First, aniline is neutralized with concentrated hydrochloric acid in aqueous solution at 100°C to form aniline hydrochloride. This solution is cooled to 15°C, a 40 percent formaldehyde solution is added, and the resulting mixture is then heated at 55 to 60°C for 4 hours. The reaction mixture is chilled again, and the product is precipitated out with dilute ammonium hydroxide. The product may be purified further by recrystallization from alcohol or water.

EXTRACTION				
Parameter	Data			
Life cycle description:	Early uses had largely to do with its disinfectant properties. It found uses as an embalming fluid and in disinfectant soaps and cleaning agents. In the furniture industry, it was incorporated in animal products: glues as a bactericide and as a preservative of wood. And, in the leather industry it is used as a disinfectant and tanning agent. An early use, developed in the Netherlands, was the treatment of flowers, in particular narcissus, bulbs against fungal rot. Formaline has been and is still extensively used as a ground disinfectant in the flower bulbs industry and is incorporated in disinfectants, insecticides and fungicides. The major uses of FA and its polymers are in the synthetic resin industry and in the manufacture of pentaerythritol and hexamethylenetetramine. Over 50% of the FA produced is used in the manufacture of resins. The resins have a wide variety of uses in glues, formed plastics, coatings, etc.

Parameter	Data			
Production, import, or use volume:	Total annual capacity for production in the United States in 1998 was 11.3 billion 11 pounds. The primary method of manufacture is from methanol with either silver or a metal oxide as catalyst (ATSDR 1999). Most formaldehyde produced in the United States (23%) is used in /urea-formaldehyde resins. Other uses include phenolic resins (19%), acetylenic chemicals (12%), polyacetal resins (11%), methylene diisocyanate (6%), pentaerythritol (5%), urea formaldehyde concentrates (4%), hexamethylenetetramine (4%), melamine resins (4%), and miscellaneous (12%) (ATSDR 1999). The phenolic, urea, and melamine resins are used in the manufacture of plywood, fiberboard, and particle board. Worldwide production in 2000 was 21, 547 thousand tons (IARC 2006).”			
Comments:	Production data is ATSDR and IARC.

Study Citation:	U.S. EPA, (1985). Preliminary assessment of health risks to garment workers and certain home residents from exposure to formaldehyde (draft).			
HERO ID:	5901066			
Conditions of Use:	commercial use			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	Over the last 30 years, the annual production and domestic use of formaldehyde in the United States has gone up fivefold from 1 billion pounds. The chemical is not imported in any appreciable quantities. The 1983 commercial production of HCHO amounted to about 6 billion pounds. The major derivatives are urea-HCHO resins, phenol-HCHO resins, acetal resins, and butanediol. The urea- and phenol-HCHO resins account for about 53 percent of HCHO production. Adhesives and plastics are the major end uses.			
Life cycle description:	HCHO's major non-consumptive uses (the chemical identity of the HCHO does not change) are (1) disinfectant, (2) preservative, (3) deodorant, and (4) textile and paper uses. The major pseudo-consumptive uses (the chemical identity of HCRO does change, but it is not irreversibly altered) are (1) urea-HCHO resins which are used in fiberboard, particleboard, plywood, laminates, urea-HCHU foams, r molding compounds, and paper, textiles, and protective coatings: (2) urea-HCHO concentrates which are used to produce time-release fertilizers, and (3) nexamethylenetetramine which is used as a special anhydrous form of HCHO to cure resins and to treat textiles and rubber. The major consumptive uses (uses in which HCHO serves as a feedstock for the preparation of other chemicals) are (1) melamine-HCHO resins which are used for molding compounds, fiberboard, particleboard, plywood, laminates, paper and textiles, (2) phenol-HCHO resins which are used in fiberboard, particleboard, plywood molding compounds, and insulation: (3) pentaerythritol which is used to produce alkyd resins, (4) 1,4-butanediol which is used to produce tetrahydrofuran, (5) acetal resins which are used in the manufacture of engineering plastics, and (6) trimethylolpropane which is used in the production of urethanes.			
Process description:	Commercially, HCHO is produced from the catalytic oxidation of methanol, using either silver oxide or a mixed-metal oxide as the catalyst. Processes accounting for the indirect production of HCHO include the photochemical oxidation of airborne hydrocarbons released from incomplete combustion processes. The direct production of HCHO during incomplete combustion of hydrocarbons in fossil fuels and refuse, and certain natural processes.			
Chemical concentration:	Pure monomeric formaldehyde is a colorless, pungent gas at ordinary temperatures. Aqueous formaldehyde, called formalin, is a clear, colorless solution containing about 37 percent by weight of dissolved formaldehyde in water, usually with 10 to 15 percent methanol added to prevent polymerization.

Study Citation:	U.S. EPA, (1984). Letter from Wycon Chemical co. to USEPA regarding comments on methylourea and urea-formaldehyde resins.			
HERO ID:	5906957			
Conditions of Use:	processing			
EXTRACTION				
Parameter		Data		
Production, import, or use volume:		During the time of the article, Wycon was producing 28,000 tons of urea prills annually. The yearly consumption of UF-71 mixture was about 240 tons.		
Life cycle description:		Urea/formaldehyde concentrate, known as UF-21, was utilized to promote anticaking urea prill product.		
Process description:		The UF-71 is shipped to the Wycon plant by truck in completely enclosed tanks. From the truck, the material is pumped into an enclosed tank for storage until needed. F-71 is then piped from the storage tank into the urea plant where the UF-71 is injected into the urea product just prior to the prilling operation. During the prilling processing, the heat involved with drying and hardening the molten solid urea into spherical pellets also polymerizes virtually all of the UF resin. The small resulting percentage of chemically inert polymerized resin in the urea prills prevents the caking of the prills.		
Chemical concentration:		UF-71 is a mixture of 50.5% formaldehyde, 20.5% urea, and 29% water.

Study Citation:	U.S. EPA, (1999). Flexographic printing - generic scenario for estimating occupational exposures and environmental releases: Draft.		
HERO ID:	6385709		
Conditions of Use:	commercial use: chemical substances in packaging, paper, plastics and hobby products.		
EXTRACTION			
Parameter	Data		
Process description:	Printing ink is typically received at a flexographic facility in 55 gallon drums and is pumped into a dispensing system or poured into 5 gallon ink cans in the ink preparation room. Each 5 gallon can is capped and carried to the press where it is opened and poured into an enclosed ink sump at press side. The ink can itself may alternatively serve as the sump. The ink is then pumped from the ink sump to an enclosed chamber which may or may not empty into an open drain pan.Next, the press is prepared for production (i.e., the makeready process). During makeready, a sample of the substrate is run through the press to allow for correction of the printing quality and the sample is then recycled or disposed. The substrate is then run through the press for the actual production run. At the conclusion of the run, the unused ink is pumped out of the ink chamber back into the sump. The “ink consumed” during makeready and production (i.e., the difference between the amount of ink added to the ink chamber and the amount removed from the ink chamber at the end of the run) either remains on the rollers, is released to the air, or is printed onto the substrate. For purposes of the CTSA, “ink consumed” includes only the ink printed on the substrate or released to air (all other releases, including container residual were considered negligible and were outside the scope of the study). Following a production run, the ink rollers and ink chamber are cleaned with solvent (for solvent-based and UV-cured inks) or water (for water-based inks). The solvent cleaning solutionmay be reused and is eventually disposed as a hazardous waste and incinerated or burned for energy recovery. The water cleaning solution may be reused and is eventually disposed as a hazardous or non-hazardous waste.		
Throughput:	Ink consumption rates vary by color of the ink; white inks have significantly higher consumption rates than the other colors, with green and blue inks having slightly higher consumption rates than magenta and cyan inks. Press speed also greatly affects the amount of ink consumed. All estimates in the CTSA assumed a press speed of 500 feet per minute for all three formulation types, which will result in the highest consumption, release, and exposurelevels. With this press speed, ink consumption rates are approximately the same between different formulation types. Model runs using industry-supplied data associated with varyingpress speeds of 336 ft/min, 380 ft/min, and 466 ft/min for UV-cured, water-based, and solvent-based formulations, respectively, show a reduction in ink consumption rates and environmental releases of 32.8%, 24%, and 6.8%, respectively.		
EVALUATION			
Domain	Metric	Rating	Comments
Domain 1: Reliability	Metric 1: Methodology	High	The report uses sound methods that are from frequently used sources (EPA) and are generally accepted by the scientific community, and associated information does not indicate flaws or quality issues.
Domain 2: Representativeness	Metric 2: Geographic Scope	High	The data are from the United States.
	Metric 3: Applicability	Medium	Printing inks, is for an occupational scenario within the scope of the risk evaluation, but no formaldehyde specific information.
	Metric 4: Temporal Representativeness	Low	1999, the report is more than 20 years old.
	Metric 5: Sample Size	Low	No statistics are provided.
Domain 3: Accessibility/ Clarity	Metric 6: Metadata Completeness	High	Assessment or report clearly documents its data sources (most of the information is from the CTSA), assessment methods, results, and assumptions.
Domain 4: Variability and Uncertainty

Study Citation:	U.S. EPA, (2003). Estimating 2003 building-related construction and demolition materials amounts.			
HERO ID:	6388382			
Conditions of Use:	construction and demolition materials			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	In 2003, the value of new residential construction put-in-place totaled \$353 billion. Average construction cost per area was \$76.80/ft2. The total estimated C&D generation amount for residential construction of 10 million tons in 2003. (section 2.1.1). The 2003 value of new nonresidential building construction put-in-place was almost \$257 billion. Average construction costs in 2003 was \$111/ft2. C&D materials estimated generation was 5.01 million tons for nonresidential construction (section 2.1.2). The total amount of residential demolition materials generated in 2003 was estimated to be 19 million tons (section 2.1.4). It is assumed that 65 million tons of nonresidential demolition materials were generated in 2003 (section 2.1.4). The total residentialrenovation generation, from the improvement or replacement projects itemized above, was estimated to be 37.8 million tons in 2003 (section 2.1.5). Total nonresidential renovation materials generated was estimated to be 29 million tons in 2003 (section 2.1.6).			
Process description:	Construction and demolition (C&D) materials are generated when new structures are built and when existing structures are renovated or demolished (including deconstruction activities).Structures include all residential and nonresidential buildings, as well as public works projects, such as streets and highways, bridges, utility plants, piers, and dams. (pg 5 of 60)			
Throughput:	Throughput of Mixed C&D Plants• Tons Processed (All): 1,768,000 TPY• Size Range: 7,000 – 485,000 TPY• Annual Throughput Reported:– Avg. HERO ID:	7310513			
Conditions of Use:	Paint/Varnish Manufacturing (6.4)			
EXTRACTION				
Parameter	Data			
Process description:	”The manufacture of paint involves the dispersion of a colored oil or pigment in a vehicle, usually an oil or resin, followed by the addition of an organic solvent for viscosity adjustment. Only the physical processes of weighing, mixing, grinding, tinting, thinning, and packaging take place. No chemical reactions are involved. These processes take place in large mixing tanks at approximately room temperature. The manufacture of varnish also involves the mixing and blending of various ingredients to produce a wide range of products. However in this case, chemical reactions are initiated by heating. Varnish is cooked in either open or enclosed gas-fired kettles for periods of 4 to 16 hours at temperatures of 93 to 340°C (200 to 650°F).” pg. 29/162

HERO ID:	7315820			
Conditions of Use:	Application of paints and coatings (4.2.2.1)			
EXTRACTION				
Parameter	Data			
Process description:	”Toll operations fill orders to various manufacturer specifications, and thus change coating and solvent conditions more frequently than do captive companies, which fabricate and coat products within a single facility and which may operate continuously with the same solventsPDF pg 1-2 describe conventional spray, hot airless spray, roller coating, knife coating, rotogravure printing and dip coating”			
Chemical concentration:	”Conventional coatings contain at least 30 volume percent solvents to permit easy handling and application. They typically contain 70 to 85 percent solvents by volume. These solvents may be of 1 component or of a mixture of volatile ethers, acetates, aromatics, cellosolves, aliphatic hydrocarbons, and/or water. Coatings with 30 volume percent of solvent or less are called low solvent or ””high solids”” coatings. Waterborne coatings, which have recently gained substantial use, are of several types: water emulsion, water soluble and colloidal dispersion, and electrocoat. Common ratios of water to solvent organics in emulsion and dispersion coatings are 80:20 and 70:30.Two-part catalyzed coatings to be dried, powder coatings, hot melts, and radiation cured (ultraviolet and electron beam) coatings contain essentially no volatile organic compounds (VOC), although some monomers and other lower molecular weight organics may volatilize. (Pg 1)”

Conditions of Use:	Application of paints and coatings (4.2.2.6)			
EXTRACTION				
Parameter	Data			
Process description:	”A variety of low solvent coatings, with negligible emissions, have been developed for some uses to form organic resin films equal to those of conventional solventborne coatings. They can be applied up to 1/8 inch thick (usually by reverse roller coating) to products like artificial leather goods, book covers, and carbon paper. Smooth hot melt finishes can be applied over rough textured paper by heated gravure or roll coaters at temperatures from 65 to 230°C (150 to 450°F).Plastic extrusion coating is a type of hot melt coating in which a molten thermoplastic sheet (usually low or medium density polyethylene) is extruded from a slotted die at temperatures of up to 315°C (600°F). The substrate and the molten plastic coat are united by pressure between a rubber roll and a chill roll which solidifies the plastic. Many products, such as the polyethylene-coated milk carton, are coated with solvent-free extrusion coatings.Figure 4.2.2.6-1 shows a typical paper coating line that uses organic solventborne formulations. The application device is usually a reverse roller, a knife, or a rotogravure printer.Knife coaters can apply solutions of much higher viscosity than roll coaters can, thus emitting less solvent per pound of solids applied. The gravure printer can print patterns or can coat a solid sheet of color on a paper web.Ovens may be divided into from 2 to 5 temperature zones. The first zone is usually at about 430°C (110°F), and other zones have progressively higher temperatures to cure the coating after most solvent has evaporated. The typical curing temperature is 120°C (250°F), and ovens are generally limited to 200°C (400°F) to avoid damage to the paper. ”

Study Citation:	U.S. EPA, (1995). AP-42: Chapter 4.12 - Manufacture of Rubber Products.			
HERO ID:	7315841			
Conditions of Use:	Rubber Manufacturing			
EXTRACTION				
Parameter	Data			
Life cycle description:	Many of the rubber manufacturing facilities in the United States produce pneumatic tires for automobile, trucks, airplanes and farm machinery. However, many rubber manufacturing facilities produce other engineered rubber products.			
Process description:	Initially, the raw rubber is mixed with several additives. The mixed rubber is often milled and transferred to an extruder where it can be combined with other rubbers. Strengthening fibers are typically coated with mixed rubber using a calendar. The extruded rubber and rubber coated materials are then assembled into a final shape and cured. It is during the curing process that the rubber vulcanizes (crosslinks), producing the characteristic properties of finished rubber. Once the final product is cured, it is often ground to remove rough surfaces and/or to achieve symmetry.			
Throughput:	Batches ranging from a two-pound laboratory mixer, to a 200-pound pilot scale system up to a 500-pound production mixer.			
Chemical concentration:	Provides 23 rubber compound recipes, including amounts of each chemical used.

Parameter	Data			
Process description:	Urea Product Manufacturing: Injection of formaldehyde additives into the liquid or molten urea before solids formation. Formaldehyde reacts with urea to form methylenediurea, which is the conditioning agent. Additives reduce solids caking during storage and urea dust formation during transport and handling. The majority of solid urea product is bulk shipped in trucks, enclosed railroad cars, or barges, but approximately 10 percent is bagged. (pdf pg. 2) Solid urea product is used for use as fertilizer or protein supplement in animal feed, and in plastics manufacturing.Normal Superphosphates: Phosphate rock and sulfuric acid reaction, product is granulated then sold as fertilizer. Full process on pdf pg. 1			
Comments:	Chapter 8 contains 13 subsections, a word search for 'formaldehyde' only returned hits in Section 8.2 Urea, 8.5.1 Normal Superphosphates ,8.5.2 Triple Superphosphates. Only these subsections were reviewed for extraction and evaluation.			
EVALUATION				
Domain		Metric	Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	Report uses high quality data that are from frequently used sources (EPA) and are generally accepted by the scientific community.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The data are from the United States
	Metric 3:	Applicability	Medium	Report is for an occupational scenario (fertilizer manufacturing), which is in scope but most of the information is not specific to formaldehyde
	Metric 4:	Temporal Representativeness	Low	The report is more than 20 years old.
	Metric 5:	Sample Size	N/A	N/A- only process description extracted.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Uncertainty is not addressed. Report provides only a limited discussion of variability in different process operations.

Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	Assessment uses high quality information/data from frequently-used sources.
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	AP-42 is based on U.S. data
	Metric 3:	Applicability	Medium	Data is for an in-scope occupational scenario; however, data is general and not specific to a chemical.
	Metric 4:	Temporal Representativeness	Low	Assessment was published in 2004, but is based on data that is greater than 20 years old.
	Metric 5:	Sample Size	Medium	Sample distribution characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	All data sources, methods, results, and assumptions are clearly documented.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	Uncertainty not addressed. Variability is addressed by considering different asphalt plant types and processing methods.
Overall Quality Determination			Medium	

Study Citation:	U.S. EPA, (2016). Federal research action plan on recycled tire crumb used on playing field and playgrounds. Status report.			
HERO ID:	9102524			
Conditions of Use:	Toys, playground, and sporting equipment			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	An estimated 4.77 million tons of waste tires were generated in 2013, and 40.5 percent, or 1.93 million tons, were recoveredthrough recycling and production of retreaded tires.Approximately 975,000 tons of scrap tires (i.e., approximately 59.5 million tires) were used in the ground rubber applications market, which includes the manufacture of new rubber products, rubber-modified asphalt, and playground and sports surfacing.			
Process description:	Two tire recycling processes, (1) ambient and (2) cryogenic, are used to create tire crumb rubber in the 10- to 20-mesh (0.84- to 2.0-mm) size, which is generally the size used in synthetic turfinfill.The ambient process uses granulation or cracker mills to produce tire crumb rubber at room temperature (Scrap Tire News, 2016). Cracker mills use revolving rollers with serrations in themto size-reduce the tires. Once the granules are produced, they are fed through screens and sorted to the appropriate size (Scrap Tire News, 2016). The cryogenic process uses liquid nitrogen to freeze partially shredded tires, which then are fed into a hammer mill to create tire crumb rubber.Current generation synthetic turf fields are typically constructed with a bottom gravel/stone base layer to allow for drainage (STC, 2011). On top of the drainage layer lies the turf component,which is composed of multi-layered polypropylene and urethane backing material with polyethylene fiber blades. Sometimes a pad can be used for additional cushioning on a field (STC, 2011).			
Number of sites:	Currently, there are between 12,000 and 13,000 synthetic turf recreational fields in the United States, with 1,200 – 1,500 new installations each year.There are approximately eight major synthetic field installers in the United States.

EXTRACTION

Parameter	Data
Process description:	Separation Processes - The first phase in petroleum refining operations is the separation of crude oil into its major constituents using 3 petroleum separation processes: atmospheric distillation, vacuum distillation, and light ends recovery (gas processing). Crude oil consists of a mixture of hydrocarbon compounds including paraffinic, naphthenic, and aromatic hydrocarbons with small amounts of impurities including sulfur, nitrogen, oxygen, and metals. Refinery separation processes separate these crude oil constituents into common boiling-point fractions. Conversion Processes - To meet the demands for high-octane gasoline, jet fuel, and diesel fuel, components such as residual oils, fuel oils, and light ends are converted to gasolines and other light fractions. Cracking, coking, and visbreaking processes are used to break large petroleum molecules into smaller ones. Polymerization and alkylation processes are used to combine small petroleum molecules into larger ones. Isomerization and reforming processes are applied to rearrange the structure of petroleum molecules to produce higher-value molecules of a similar molecular size. Fluidized-bed Catalytic Cracking (FCC) - The FCC process uses a catalyst in the form of very fine particles that act as a fluid when aerated with a vapor. Fresh feed is preheated in a process heater and introduced into the bottom of a vertical transfer line or riser with hot regenerated catalyst. The hot catalyst vaporizes the feed, bringing both to the desired reaction temperature, 470 to 525°C (880 to 980°F). The high activity of modern catalysts causes most of the cracking reactions to take place in the riser as the catalyst and oil mixture flows upward into the reactor. The hydrocarbon vapors are separated from the catalyst particles by cyclones in the reactor. The reaction products are sent to a fractionator for separation. The spent catalyst falls to the bottom of the reactor and is steam stripped as it exits the reactor bottom to remove absorbed hydrocarbons. The spent catalyst is then conveyed to a regenerator. In the regenerator, coke deposited on the catalyst as a result of the cracking reactions is burned off in a controlled combustion process with preheated air. Regenerator temperature is usually 590 to 675°C (1100 to 1250°F). The catalyst is then recycled to be mixed with fresh hydrocarbon feed. Moving-bed Catalytic Cracking- In the moving-bed system, typified by the Thermafor Catalytic Cracking (TCC) units, catalyst beads (~0.5 centimeters [cm] [0.2 inches (in.)]) flow into the top of the reactor, where they contact a mixed-phase hydrocarbon feed. Cracking reactions take place as the catalyst and hydrocarbons move concurrently downward through the reactor to a zone where the catalyst is separated from the vapors. The gaseous reaction products flow out of the reactor to the fractionation section of the unit. The catalyst is steam stripped to remove any adsorbed hydrocarbons. It then falls into the regenerator, where coke is burned from the catalyst with air. The regenerated catalyst is separated from the flue gases and recycled to be mixed with fresh hydrocarbon feed. The operating temperatures of the reactor and regenerator in the TCC process are comparable to those in the FCC process. Treating Processes - Petroleum treating processes stabilize and upgrade petroleum products by separating them from less desirable products and by removing objectionable elements. Undesirable elements such as sulfur, nitrogen, and oxygen are removed by hydrodesulfurization, hydrotreating, chemical sweetening, and acid gas removal. Treating processes, employed primarily for the separation of petroleum products, include such processes as deasphalting. Desalting is used to remove salt, minerals, grit, and water from crude oil feedstocks before refining. Asphalt blowing is used for polymerizing and stabilizing asphalt to improve its weathering characteristics. Feedstock And Product Handling - The refinery feedstock and product handling operations consist of unloading, storage, blending, and loading activities. Auxiliary Facilities - A wide assortment of processes and equipment not directly involved in the refining of crude oil is used in functions vital to the operation of the refinery. Examples are engines and boilers, waste water treatment facilities, hydrogen plants, cooling towers, and sulfur recovery units. Products from auxiliary facilities (clean water, steam, and process heat) are required by most process units throughout the refinery. Compressor Engines - Many older refineries run high-pressure compressors with reciprocating and gas turbine engines fired with natural gas. Natural gas has usually been a cheap, abundant source of energy. Examples of refining units operating at high pressure include hydrodesulfurization, isomerization, reforming, and hydrocracking. Internal combustion engines are less reliable and harder to maintain than are steam engines or electric motors. For this reason, and because of increasing natural gas costs, very few such units have been installed in the last few years. More process descriptions in source.

Conditions of Use:	Processing aids, specific to petroleum production in all other basic chemical manufacturing			
EXTRACTION				
Parameter	Data			
Process description:	Natural gas is considered "sour" if hydrogen sulfide (H2 S) is present in amounts greater than 5.7 milligrams per normal cubic meters (mg/Nm3) (0.25 grains per 100 standard cubic feet [gr/100 scf]). The H2S must be removed (called "sweetening" the gas) before the gas can be utilized. If H2S is present, the gas is usually sweetened by absorption of the H2S in an amine solution. Amine processes are used for over 95 percent of all gas sweetening in the United States. Other methods, such as carbonate processes, solid bed absorbents, and physical absorption, are employed in the other sweetening plants.

HERO ID:	9263849			
Conditions of Use:	Adhesives and sealant chemicals in wood product manufacturing			
EXTRACTION				
Parameter	Data			
Life cycle description:	Softwood plywood is used for wall siding, sheathing, roof decking, concrete formboards, floors, and containers. Hardwood plywood is used for interior applications such as furniture, cabinets, architectural millwork, paneling, flooring, store fixtures, and doors. Fiberboard is a low-density insulation board used for housing, roofing, and office furnishings. Hardboard is similar to fiberboard, except that hardboard is more dense than fiberboard. Hardboard is used for applications in housing (e.g., exterior siding, garage doors, and interior door facings), furniture, store fixtures, automotive interiors, and toys.			
Process description:	Softwood plywood is manufactured by gluing several layers of dry softwood veneers together with an adhesive. Hardwood plywood is made of hardwood veneers bonded with an adhesive. The outer layers (face and back) surround a core which is usually lumber, veneer, particleboard, or medium density fiberboard. Hardwood plywood may be pressed into panels or plywood components (e.g., curved hardwood plywood, seat backs, chair arms, etc.). Full process descriptions for plywood manufacturing are in section 10.5.2 pg 2-3. Particleboard is defined as a panel product manufactured from lignocellulosic materials, primarily in the form of discrete particles, combined with a synthetic resin or other suitable binder and bonded together under heat and pressure. Full process descriptions for plywood manufacturing are in section 10.6.2 pg 1-3. Fiberboard and Hardboard is made from wood chips which are first softened in a pressurized steam vessel (digester) and then refined or pulped into wood fibers. The fibers may then be mixed with resin, formed into mats, and pressed and/or dried to form panel products. Full process descriptions in section 10.6.4.2 pg. 1-8. Waferboard (WB) and oriented strandboard (OSB) belong to the subset of reconstituted wood panel products called flakeboards. They are structural panels made from wood wafers specially produced from logs at the plant. Full process descriptions in section 10.6.1.2 pg. 1-3.			
Comments:	Evaluated only sections expected to be relevant to formaldehyde COUs.

EXTRACTION				
Parameter	Data			
Life cycle description:	formaldehyde manufacture-> resin manufacture->particleboard manufacture-> **cabinet manufacture**-> installation-> consumer use (household use). [De-veloped based on report]			
Process description:	The cabinet manufacturing process begins with cutting veneered particle board sheets and natural grain wood (from the raw material storage area) to the desired size for use as cabinet components. These components are then further worked in the millroom as necessary using power planers, groovers, notchers, sanders, and drills in preparation for primary assembly. In the primary assembly operation, the cabinet cases and their corresponding doors and drawer fronts are assembled separately using wood glue and industrial staplers. These sub-assemblies are then sent to the finishing department where there are two separate finishing lines; one for cabinet cases, the other for doors and drawer fronts . In the finishing operation, the exterior natural grain wood surfaces are sprayed in spray booths with: a stain, a sealer, and a glossy top coat . Some of the doors and drawer fronts are sprayed with a stain which is then handwiped. The sub-assemblies are dried in gas-fired ovens after the application of each spray finish. The finished sub-assemblies are then moved to the final assembly department where the doors, drawers and accessory hardware are attached to the cabinet case. The completed cabinets are then boxed and sent to the warehouse for storage prior to shipment. (5/30)

Study Citation:	Wan, H., Wang, X.M., Barry, A., Shen, J. (2014). Recycling wood composite panels: Characterizing recycled materials. BioResources 9(4):7554-7565.			
HERO ID:	3072990			
Conditions of Use:	Recycling			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	(USA 2013) Consumption of 2.87 billion square feet of particleboard and 2.66 billion square feet of medium density fiberboard. In 2014 the consumption of PB and MDF panels will increase by 5.8% and 13.7%, respectively			
Life cycle description:	the wood composite industry in the USAand Canadais reluctant to use more than 15% of recycled or downgraded UF resin bonded panel materialsin manufacturing, for example, PBpanels			
Process description:	The procedure of steam explosion of recycled wood composite materials can be described as follows: 1) a mechanical feeder (a feeder hopper) supplies recycled materials to a pressurized vessel with a reciprocating piston in such a manner that the pressure difference can be maintained on a continuous basis. The feeder hopper is equipped with a water sprinkler system that supplies water to the material prior to its entry into the reactor vessel. The stainless steel pressure vessel measures 0.6 m in diameter and about 7 m in length with a screw conveyor running at 34 rpm through its interior. In this experiment, a certain amount of tap water was added such that the final steam-exploded recycled materials would reach moisture content around 65%. 2) As the material is fed in the vessel, saturated steam at a maximum temperature of 235 C is applied simultaneously to the vessel. The screw conveyor carries the materials through the reactor at a designated rate and mixes and shreds the materials into smaller sized particles. 3) Once the steam treatment time is reached, an electronic valve can be used to quickly open and close the pressurized vessel to allow the material to move to a material collection cyclone. The pressure difference between the vessel and the atmosphere creates an explosion effect and further breaks the materials down into fibers. The steam explosion treatment time and temperatures used are presented in Table 2 - MDF time: 0.8 minutes, 227 C; PB time: 0.8 minutes, 227 C. Process used in study were sampled of 1000 g of downgraded PB or the same amount of MDF were impregnated with the same amount of 05% BTCA and 0.5% NaH2PO2 water solution under a vacuum (700 mmHg) for 10 min and then autoclaved using a Medalist 200 at 113 C for 20 min. So the retention of the solution of treated panels was 100%. Prep of hammermilled particles, 1-1/2 inch wide PB strips were cut from 1-1/2 inch thick recycled PB panels and proken down into particles by a Blue Streak hammermill of 25 HP at 1765 rpm, without screening. It took approximately 45 s to break down 10 PB strips about 30 inches long.			
Chemical concentration:	MDF panels - 12% Urea formaldehyde (UF) on face of panel, 10% on core layers; PB - 10% UF on face, 8% on core layers.

EXTRACTION

Parameter	Data
Process description:	The flocked upholstery fabric manufactured by Microfibres consists of three basic components: a backing fabric, adhesive, and cut nylon fibers. A complex process brings these three basic components together into a final product. In recent years, only nylon flock has been used at the Microfibres plant, but both nylon and polyester flock is produced. All polyester flock produced at the plant is bagged for shipment to other plants. To produce flock, nylon (or polyester) “tow”—a loose rope of thin continuous nylon (or polyester) fibers—is dyed and coated with a finish before being cut, dried, screened, and bagged as flock. The flock is later deposited on cotton–polyester fabric backing coated with an acrylic latex adhesive by a process using an electrostatic field to align the falling flock fibers. After heat–curing of the adhesive, the flocked fabric may be subjected to finishing, mechanical embossing, and/or water–based ink–screen printing. A number of different departments perform specific tasks in producing the final product. Dye House Department At the Continuous Dyer, bulk “tow” (which arrives in boxes or on spools) is dipped in a dye bath, fixed with steam, and placed damp in large boxes for temporary holding. At the Recycle Area, located elsewhere in the plant, workers from the Dye House Department wash and dye waste flock from this and other Microfibres plants. Raycote Department “Tow” received from the Dye House Department is rinsed in a hot water bath, dipped in a finishing bath (containing tannic acid, an ammonium ether of potato starch, and a fatty alcohol derivative), and cut into flock by machines called rotary precision cutters (RPCs). The flock is then dried, screened, and stored in large bags for future use in this and other flocking plants. Compounding Department In the Compounding Department, acrylic latex adhesives are mixed. In addition, a fabric protector (Scotchgard®) and softening compounds are also prepared for use in finishing processes. Compounding Department workers deliver the prepared compounds to the areas of use and remove waste adhesive and empty containers. Coating Department The Coating Department consists of two roll–to–roll coating ranges (Ranges 1 and 2), two embossing ranges, and a printing range. (Note: when the term “Range” is used in this report without specifying the particular type, it refers to the coating range.) At each coating range, polyester/cotton fabric backing is coated with adhesive. The backing enters the flocking module located in a temperature– and humidity–controlled flocking room. Flock is manually dumped into hoppers and a desiccant powder may be added and mixed in to control moisture content and prevent clumping. In the module (an enclosed unit where flock is applied), the flock–desiccant mixture is dispersed above the adhesive–coated backing in an electrostatic field that aligns the falling flock fibers so they embed in the adhesive at an angle more or less perpendicular to the backing. Upon exiting the flocking room, the fabric is passed through a gas–fired curing oven, sprayed with either a fabric protector or a softening compound, returned through the oven, inspected, and taken up onto a roll. The fabric can then be sent to be processed at an embossing range or at a printing range that utilizes water–based inks, or can be sent directly to shipping. Between process runs that differ with respect to flock texture (e.g., length and/or diameter) or color, the affected Range must be cleaned of residual flock prior to starting the new run. A “blow–down” involves the use of compressed air to clear loose flock from the flocking module, and from the flocking room walls, floor, and other equipment. Workers conducting blow–downs begin this process on the module and blow out any loose flock in or on the module, then blow the flock from one side of the room to the other, and finally bag the loose flock for disposal. The frequency of blow–downs varies with the production schedule. On occasion, it may be necessary to perform several blow–downs per shift. Other Departments Shipping Department personnel utilize forklifts to retrieve finished rolls of fabric from production areas and bring them to the loading area where they are placed in trucks for shipment. In addition to short–term storage space in the plant, an off–site warehouse is located in a nearby town. Maintenance Department workers maintain equipment throughout the facility. Office personnel are located within offices in the production building, as well as in a separate building nearby.

HERO ID:	6121060			
Conditions of Use:	Laboratory chemicals (sterilization of respiratory equipment)			
EXTRACTION				
Parameter	Data			
Process description:	Low temperature steam plus formaldehyde (LTSF). The temperature of the load must not exceed around 72°C; there must be even penetration of the load; the load must retain at most a very low and preferably an undetectable concentration of formaldehyde or its polymers; the atmosphere at the steriliser door and drains must at no time exceed 2 parts per million. Optimum sterilising conditions will be achieved if all surfaces of the load are in continuous contact with monomeric formaldehyde evenly mixed with dry saturated steam. It seems desirable to minimise the production of condense and to remove it as soon as it forms. The STERILISING stage consists of 40-60 steam/formalin pulses between 50-250 TORR with 0.2ml formalin/cu. ft.lpulse. This period takes between 40-60 minutes and varies with the load size. Removal of formaldehyde and its polymers can only effectively bc achieved by steam pulses or chemical neutralization followed by air pulses. DRYING is achieved by about five air/vacuum pulses between 50-760 TORR.			
Chemical concentration:	Formaldehyde alone requires concentrations of over 1000 mg/litre to be sporicidal. With both steam and formaldehyde, concentrations as low as 3 mg/litre are effective at killing spores. Where many continuous pulses are used the amounts of formalin inlroduced can be as low as 0.2ml per cubic foot sterilizer space per pulse.

Process description:	Bush StreetThere is one urethane foaming line. The front of the line with the foam head is called the 'Bridge' and the end of the line is designated as the 'lower end.' Chemicals are stored in an area below the bridge in tanks and drums. Batches of chemical additives (surfactants, fire resistant, blowing agents, dyes, catalysts, etc.) are mixed together in the 'activation room' by an activator and assistant, (compounders), and pumped to the bridge, in a closed system, to combine with toluene diisocyanate (TOI) and a polyester resin. All the ingredients mix and flow through thefoamer head onto a plastic-coated paper conveyor system which is controlled by the foamer operator who maintains the rate and density of foam application. The foam reacts, exothermically, as the process flows towards the lower end. The conveyor system is partially enclosed and is ventilated. As the reacting foam solidifies (polymerizes), into flat slabs, it passes a series of heat lamps which can be used to facilitate skin formation for certain batches ofproduct. At the lower end the paper is removed, ('paper take off'), and the solid polyurethane moves onto a roller system which transports it to a cutting process, ('saw'). The continuous band saw is operated by a 'cutter' who adjusts the machine to achieve specified lengths of foam and also labels each piece as it is cut. The cut pieces are then removed from the roller conveyor and stacked, by color, for ambient curing. Cured foam slabs are cut to desired thicknesses by the 'duplex' operation and then are restacked forshipment. Some of the polyurethane is processed on-site for specialty products such as gaskets, shoulder pads, and hair curlers. Overall, the foaming process is a batch operation.JessupThere is one urethane foam process line similar to that at Bush street. The chemical additives are mixed in the activation room, pumped to the Bridge foaming/pouring head where the mixture combines with TOI and resin, and is metered through the pouring head onto a conveyor covered with a continuously fed plastic coated paper. The paper in this process however is slowly curled up on the sides so that the reacting foam becomes cylindrical in shape upon solidification (polymerization). The reacting foam proceeds along the partially enclosed, exhaust-ventilated, conveying system, through the 'paper take off' station and onto a roller system leading to the cutting station. As the urethane cylinder is cut to specified lengths, it is labeled and stacked, in the 'backroom' for a four hour minimum ambient cure. The urethane cylinders are placed on a core borer which bores a hole through the cylinder's horizontal center (core) and the cylinder is mounted onto a machine which peels it into sheets of specified thickness and length. (Longer sheets can be made by heat-sealing two peeled cylinder ends together.) The peeling room is called the 'main room'. rewinds the cut sheets into a cylinder which is placed into a polyethylene bag, which is then compressed either by vacuum or mechanically, wrapped, taped, weighed and readied for shipment. Excess scraps of urethane are fed into a shredder which feeds a baler, via a roof cyclone. The baled urethane scraps are loaded by a fork lift truck into railroad cars for shipment.

Parameter	Data			
Process description:	”The process evaluated involved pattern making for women’s sportswear for size 38-50... When a garment sample is received a pattern is developed to the particular specifications and thebasic slope blocks. A draft pattern is made and a single garment is cut out, sewn, pressed and fit-tested on a live model. Appropriate corrections/ modifications are made until the right fit is obtained. Then from the basic pattern the other size patterns can be made. Multiple pattern sets can then be made on a 'lay table'. Here the patterns are laid out over a plastic sheet and 'run' paper is laid over it. The run paper contains a chemical which is light sensitive so when the lay table lights are turned on for a prescribed time the patterns’ outline is photo copied onto the run paper. The run paper is then 'developed'/copied on a photomaker machine for the master copies. The photomaker machine uses a solution calledSuper Diazol which is composed of primarily ammonium hydroxide. ... After copies of the patterns are made they can be laid out on long cutting tables, over laid with material (up to 100 layers depending on fabric density) and the patterns cut out. Cutting is performed with reciprocating electric cutters, both straight and disc. There are three cutting tables, one lay out phototable, one pattern table, and one automatic sizing table. The cut material is shipped to sewing facilities . ” (2-3/10)

EXTRACTION				
Parameter	Data			
Process description:	From the storage area, material is moved to the staging area where it is pulled out of its protective bag and allowed to sit for at least a half day before cutting. In the cutting department, the fabric is taken to either automatic spreading machines or to tables on which the fabric is hand-laid to match stripes. Occasionally, solvent-based adhesives are used to glue the pattern pieces in place. A band saw or straight knife is used to cut fabric and a rotary saw is sometimes used to cut elastic pieces. The cut pieces go to the bundling area where they are sorted into buckets (20 to 50 pieces depending on the garment to be made). Tote carts are used to transport the buckets to the sewing area. The sewing department makes the clothing; a variety of machines are used, including three-thread, single-needle, multi-needle, flat-bed hemmer, pocket setter, tacker, labels, button-holer, snap, and needle-nose. The machines used vary, depending on the garment being produced. To reduce the size of needle marks in the fabric, asolution of silicone lubricant, fabric softener, and water is used on the material. The completed garments are taken to the finishing department, where the garment is inspected for stitch quality, loose threads, matching stripes, spots, and stains. There are two spotting stations, used to remove stains from the garments, located adjacent to the sewing department. These spotting stations are used as needed. Spot removers containing trichlorethylene and perchloroethylene, and a rust stain remover containing hydrogen fluoride (8%) are used. There are local exhaust controls at each station. A heat press is used occasionally for fusible pella fabric. Some employees in this area use Johnson & Johnson Germ filter masks as protection from organic vapors and dust. After inspection, the garments are folded and packed to ship to the customer.

Process description:	Film Formation by Coalescence of Polymer Particles. Hydroxy-functional latexes can be formulated with melamine–formaldehyde (MF) resins or a water-dispersible polyisocyanate for wood and maintenance coatings.Amino Resins. MF resins are made by reacting melamine (1,3,5-triazine-2,4,6-triamine) [108-78-1] and formaldehyde [50-00-0] followed by etherification of the methylol groups using an alcohol. There are two major classes of MF resins: Class I MF resins are made using excess formaldehyde, and a high fraction of the methylol groups are etherified with alcohol. Commercial resins are mixtures of compounds, most having a single melamine unit with a large fraction of the amine groups substituted with two alkoxyethyl groups. The resins also contain oligomers having two or more triazine rings coupled with methylene ether groups and possibly with methylene groups. Various alcohols can be used. The largest volume class I resins contain a high proportion of hexamethoxymethylmelamine (HMMM) (N,N0,N00-hexamethoxymelamine). Class II MF resins are made using a lower ratio of formaldehyde to melamine, and a significant fraction of the nitrogens have one alkoxyethyl group and a hydrogen. An example of one compound present is N,N0,N00-trimethoxymethylmelamine (TMMM). Class II resins have a larger fraction of oligomers.

Parameter	Data			
Process description:	The structure of the cans is three plies of paperboard, along with an inner liner and an outside label. these five plies are held together by a water-soluble glue. After the five plies are joined, an in-line process will cut the tube (cans) to a predetermined length and the tube continues to flow, uninterrupted down the production line. Depending o the inner liner used as dictated by customer specifications, a lubricant is applied (mineral spirits or mineral oil) to release the liner from the winding and/or cutting mandrel. the cans are then automatically seamed, placed a metal top with a plastic spout on the composite can. these are then packed in corrugated cartons to ship to the customer. the metal tops mentioned above converted in the St. Paris Plant on punch presses. operations.Hand WaxAn application of was is sprayed by a machine in the back, open end of the composite can. This is done so that when the customers insert a closed device after the composite can is filled at their facility it reduces air and moisture penetration. Approximately 10% of the composite cans produced have eth was added. This manufacturing process was not a full-time production operations. the longest continuous mode of this process was 6 weeks 24 hours a day five days a work week.Auto WaxThis is a second generation of the hand waxer. The auto waxer increased production by 20 times the amount realized on the hand waxer. All materials are consistent with the hand wax operations. Composite cans are automatically fed from the production lines to the auto was operation. Two duplex spray heads operate simultaneously - spraying wax into the open end of the composite cans. Th e wax is preheated in a drum and then hand carried in open buckets to two melt tanks on the auto wax machine. mineral oil is used to cut the wax.CompounderThis machine places a strip of compound material around the outer and inner circumferences of the caulk top (metal). This is required by some customers in order to prevent air or moisture from penetrating through the base of the plastic spout off the metal as it is joined to the composite can. This equipment may be scheduled one or two days, eight hours/shift, per week.Line 2This is where paperboard plies , together with the inner liner and label are joined.

EVALUATION				
Domain	Metric		Rating	Comments
Domain 1: Reliability	Metric 1:	Methodology	High	Report uses high quality data from frequently used source, NIOSH study
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	US
	Metric 3:	Applicability	High	The report is for an occupational scenario (cardboard tube manufacture) within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	Low	1986- more than 20 years old
	Metric 5:	Sample Size	N/A	qualitative information provided
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	Information provided was derived from NIOSH site visit.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	N/A	qualitative information provided
Overall Quality Determination			High

HERO ID:	626661			
Conditions of Use:	Manufacture			
EXTRACTION				
Parameter	Data			
Production, import, or use volume:	global production 46 billion pounds US production 11 billion pounds. Commercially, formaldehyde is manufactured as an aqueous solution called formalin, usually containing 37% by weight of dissolved formaldehyde. It is commonly used as a tissue preservative or as a bactericide in embalming fluid and medical laboratories. Formaldehyde is primarily used in the production of phenol- or urea-formaldehyde resins, plastics and chemical intermediates. Such resins are commonly used in everyday products as previously stated above. Formaldehyde is also widely used in molding compounds, glass wool and rock wool insulation, decorative laminates and textile treatments.			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	The assessment or report uses high quality data
Domain 2: Representativeness	Metric 2:	Geographic Scope	High	The data are from the United States and are representative of the industry being evaluated.
	Metric 3:	Applicability	High	The report is for an occupational scenario within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	Medium	Operations, equipment, and worker activities are expected to be reasonably representative of current conditions. The monitoring data were collected (report published 2009) after the most recent PEL (1992) establishment and is more than 10 but less than 20 years old.
	Metric 5:	Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics. It is unclear if analysis is representative.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	Medium	Assessment or report clearly documents results, methods, and assumptions. Data sources are generally described but not fully transparent.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Low	The report does not address variability or uncertainty.
Overall Quality Determination		Medium

HERO ID:	3001786			
Conditions of Use:	Disposal			
EXTRACTION				
Parameter	Data			
Chemical concentration:	Wastewater from urea-formaldehyde resin production can contain up to 4000 mg/L of FA but can be even higher according to other studies: highest literature value reported is 13,000 mg/L. Wastewater obtained for this study also had 13000 mg/L but the wastewater was diluted to achieve different FA concentrations of 30, 60, 120, 450, 550, 700, 1100 and 1600 mg/L			
EVALUATION				
Domain	Metric	Rating	Comments	
Domain 1: Reliability	Metric 1:	Methodology	High	Sound method (Polish Standard PN-C-04593:1971)
Domain 2: Representativeness	Metric 2:	Geographic Scope	Medium	Poland, an OECD country
	Metric 3:	Applicability	High	The report is for an occupational scenario, disposal, within the scope of the risk evaluation.
	Metric 4:	Temporal Representativeness	High	The report is expected to capture operations, equipment, and worker activities expected to be representative of current conditions. The report is generally no more than 10 years old.
	Metric 5:	Sample Size	Medium	Distribution of samples is characterized by a range with uncertain statistics.
Domain 3: Accessibility/ Clarity	Metric 6:	Metadata Completeness	High	Assessment or report clearly documents its data sources, assessment methods, results, and assumptions.
Domain 4: Variability and Uncertainty	Metric 7:	Metadata Completeness	Medium	The report provides only limited discussion of the variability and uncertainty in the results.
Overall Quality Determination			High
